#### **Abstract**

# Timing of chromosomal alterations during tumour development

Björn Viklund

During cancer development, tumour cells will accumulate a lot of both somatic point mutations and copy number alterations. It is not unusual that affected genes have a copy number that differs from the usual two. Due to the loss of DNA repair mechanisms the cells can mutate independent from each other which gives rise to different subclones within the tumour. A tumour cell and its future daughter cells that gets an advantage in cell division speed compared to its competing neighbours, will eventually make up a large portion of the tumour. All the mutations that the subclone's most recent common ancestor acquired until the expansion will be shared across the subclone.

In this project, we have developed a method using the mutation frequencies from publicly available whole genome sequencing data, to quantify the amount of competing subclones in a sample and determining the time to its copy number duplications. This method could be further developed to be an extension to regular copy number analysis.

A heterogeneous tumour can grow faster and be more resistant to treatment. Therefore, it is important to learn more about cancer development and get a greater understanding of the order in which copy number alterations occur.

#### Populärvetenskaplig sammanfattning

En cell som så småningom utvecklas till en cancercell samlar på sig många somatiska mutationer, det vill säga mutationer som enbart kommer existera i den cellen och dess dotterceller. Mutationerna varierar från enbaspolymorfier till att hela kromosomer dupliceras eller går förlorade. Det innebär att antalet kopior av de påverkade generna ofta avviker från det normala två. Ett mål med projektet var att utnyttja helgenomsekvensering för att med hjälp av punktmutationer bestämma ungefär när kopietalsförändringar har inträffat.

I en tumör är det vanligt att vissa mutationer bara finns i en subklon av tumörcellerna. Om någon av dessa mutationer ger en ökad tillväxthastighet kommer subklonen utgöra en allt större andel av tumörcellerna.

Vi har utvecklat en metod som kan användas till att hitta eventuella subkloner, avgöra ungefär när de började växa samt hur stor andel av cellerna de utgör. Detta kan vidareutvecklas och bli en del av förbättrad kopietalsanalys.

När metoden användes för att analysera cellinjer och ett tumörprov, observerade jag att tidpunkterna för kromosomförändringar varierade mellan proverna. Fortsatta studier krävs för att utröna vilken relevans detta har för tumörutvecklingen och kliniskt beteende hos tumörerna.

# 1 Introduction

Every cell in the body is exposed to mutations. Only mutations that occur in germ cells are inherited to the offspring. All other mutations are somatic mutations, they only affect the individual cell in which the mutation occurs and its daughter cells. During cancer development, the cell that will eventually transform into a fast growing cancer cell, will have accumulated a lot of somatic mutations. These somatic mutations range from single nucleotide substitutions to whole chromosome duplications or deletions. Deletions and duplications will cause the number of copies of the genome to locally deviate from the normal two<sup>1</sup>,<sup>2</sup>.

To initiate tumour growth in colorectal cancer, it has been shown that a series of point mutation events have to occur. An initial point mutation that regularly occur in the Adenomatous polyposis coli (APC) gene will cause the cell to ease its restriction of cell division speed, giving it a slight edge compared to its neighboring cells. If another point mutation occurs in a gene such as the Kirsten rat sarcoma viral oncogene homolog (KRAS) gene, will give the cell an even greater advantage in division speed<sup>3</sup>. The next step is, the disabling of tumour suppressor genes such as the TP53 gene. This is often accomplished when one of the alleles is affected by a point mutation that removes its function, and the other is deleted. This is referred as the "Two hit hypothesis" 4. Each time a cell gains an advantageous mutation over its siblings a new subclone will form, this can occur numerous times during cancer development (Figure 1).

To study these somatic point mutations, a sample from the tumour is extracted. A tumour can contain billions of cells, including cancer cells and regular cells such as blood vessel cells. During preparation of genomic DNA to be whole genome sequenced, cells in the sample are lysed and mixed together, making the resulting DNA a mix of tumour and normal DNA. The DNA is then fragmented and sequenced as short reads, that are assembled against a reference genome. The more reads that map to a specific region the higher is the sequence coverage. Nucleotides or regions that differ from the reference genome are considered genomic variants<sup>6</sup>.

Data from whole genome sequencing can be used to identify the absolute copy numbers throughout the cancer genome, based on the two non-identical homologous chromosomes that are normally found<sup>5</sup>. Which means that the number of copies for each specific allele across the genome is known.

Access to whole genome sequence and copy number data opens the possibility to estimate when a specific copy number alteration has occurred. There is an existing method that estimates the order in which rearrangements of genomic segments have occurred, by using graph theory methods and somatic mutations<sup>7</sup>. This method is encouraged to use with high sequence coverage, upwards of 180 was recommended to achieve good performance<sup>2</sup>. Unfortunately the sequence coverage that was available during this work was on around 52. Therefore in this project we have focused on determining the time to duplication (TTD) of copy-number altered regions, and to identify the time until subclonal growth in the tumour.

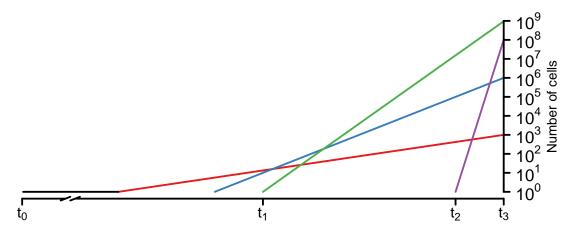

Figure 1: Schematic illustration of tumour progression into cancer. Here we assume exponential growth for each subclone and do no take any growth limiting factors into account (nearby blood vessels and nutrition, et cetera). The interval t<sub>0</sub> until t<sub>3</sub> spans from the time of initial somatic mutation  $t_0$  until the date of tumour sample collection  $t_3$ . During t<sub>0</sub> until the red line, a single cell accumulates somatic mutations during a time period (up to several decades). The red line starts the moment a rate limiting mutation in a gene, such as the APC gene, affects the cell's growth rate. This initiates the cells uncontrolled proliferation into a tumour. The blue line starts when a cell gained another mutation in for example the KRAS gene and caused the cell to proliferate faster than the red clone. At t<sub>1</sub>, a cell from either the red or blue clone gained yet another mutation that further increased the growth rate and formed the major clone at the time the samples was taken. At time t<sub>2</sub> a new rate limiting mutation occurred in one of the cells. At time t<sub>3</sub> the sample was taken, since the green clone had the largest number of cells it is considered as the primary clone. The purple clone is only one-tenth of the green clone, and therefore defined as a subclone that occupies 10% of the sample. Due to the small proportions the remaining subclones will not be detected.

# 2 Method development

Publicly available whole genome sequencing data was retrieved for the breast cancer cell lines HCC1187 and HCC2218 and patient-matched normal cell lines. Genomic DNA from four samples of human colon cancer, A01\_167, C01\_203, E01, G01\_278 and patient-matched blood or normal tissue were sequenced by Complete Genomics, see Table 1. Complete Genomics provides sequencing and reference genome assembly with their own pipeline.

The flowchart in Figure 2 shows an overview of the major steps needed for this project.

Table 1: Description of samples used in the study. MSI/MSS describes if the samples are microsatellite instable or microsatellite stable.

Name	Source	Median coverage	Mean ploidy	#point mutations	MSI/MSS
HCC1187	Breast cancer cell line	51	2.8N	18644	MSS
HCC2218	Breast cancer cell line	46	2.1N	23894	MSS
$A01_{-}167$	Primary colon cancer	53	3.5N	18711	MSS
C01_203	Primary colon cancer	51	3N	18776	MSS
E01	Primary colon cancer	60	2N	15305	MSS
$G01_{-}278$	Primary colon cancer	53	2.8N	21893	MSS

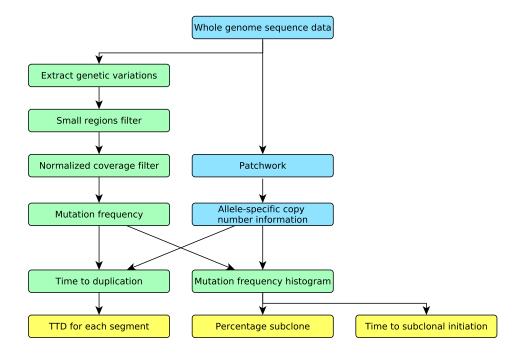

Figure 2: Flowchart describing the project. The blue boxes indicate already existing tools/data. Methods that had to be developed are marked green and the output is coloured yellow. Patchwork was used to identify the copy numbers. Genetic variations such as somatic point mutations and SNPs, and sequence coverage were extracted from the whole genome sequence data. Due to an unexpected non-random distribution of point mutations in a few of regions per sample, two filters were developed to cope with skewed results (See filtering). The mutation allele frequency is a ratio between zero and one that describes how much of the coverage each point mutation occupy. With the copy number information and the mutation frequencies, the time to duplication for each segment was estimated. The mutation allele frequency and normal diploid genomic segments were used to both determine the time to subclonal initiation, that is the time the cell that eventually grew into a subclone spent acquiring somatic mutations until a new rate limiting mutation occurred, and to estimate the proportion of subclone in the tumour.

# 2.1 Time to duplication

TTD of a segment is the proportion of time between  $t_0$  and  $t_1$  when the aberration occurred (Figure 1). A TTD-value near zero indicates an early duplication whereas a late duplication will have a TTD-value near one.

To obtain TTD-values, point mutations before and after gene duplication were extracted. If the point mutation occurred before duplication, then it may be amplified and there could be two exact copies of the point mutation. A point mutation that occurred before duplication is called as an early point mutation. A point mutation that occurred after duplication will affect only one chromosome, and is marked as a late point mutation (Figure 3). During a period of time, the segment will have accumulated several point mutations, both before and after a duplication event. If the duplication happened early, there would be a lot more late than early point mutations. If it happened late it would have few late point mutations and considerably more early point mutations.

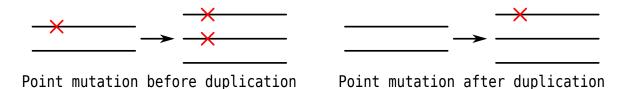

Figure 3: Visualization of point mutations before and after duplication of a segment. *Left*: Early point mutations result in amplification of the point mutation upon duplication. *Right*: Late point mutations will not be copied as they are post-duplication.

Assuming even exposure to point mutations over time, the TTD can be estimated by the ratio between the exposure of early mutations and the total exposure of mutations (Equation 1). The more copies of a segment the greater is the exposure to somatic mutations. To compensate for varying exposure, the copy number before and after duplication were taken into account (Equation 2). Figure 4 illustrates a duplication example.

$$time\ to\ duplication = \frac{early\ mutation\ exposure}{total\ mutation\ exposure} \tag{1}$$

$$time \ to \ duplication = \frac{\frac{\#early \ mutations}{early \ copy \ number}}{\frac{\#late \ mutations}{copy \ number} + \frac{\#early \ mutations}{early \ copy \ number}}$$
(2)

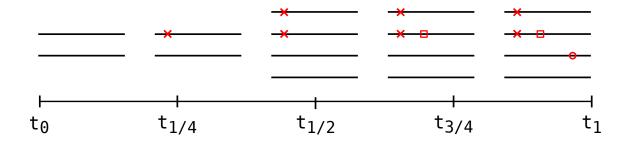

Figure 4: Visualization of time to duplication. The time  $t_0$  indicates when the cell started to accumulate somatic mutations, and  $t_1$  the time the cell was sequenced. The two segments in focus were duplicated approximately halfway along the timeline. Only one point mutation occurred before the duplication. After the duplication the mutation exists on two out of four chromosomes. During the rest of the time, two more point mutations occurred, and could only affect either one of the chromosomes. At  $t_1$  there was a total of three mutations. The exposure of point mutations were assumed to be constant per amount of DNA. Equation 2 reveals the time to duplication to be one-half.

The method described above will only discover the early mutations that have occurred on a segment that was amplified. Any unamplified segments' point mutations will only affect one copy regardless of when they occur, and therefore would not be informative. As point mutations occur randomly, an equal number should occur on both homologous chromosomes before duplication. The observed number of duplicated early mutations was used to estimate the number of early unduplicated mutations.

# 2.2 Mutation allele frequency

To determine if a point mutation occurred early or late with whole genome sequencing data, the mutation allele frequency was used. The frequency was defined as the ratio between the coverage of the mutation and the total coverage on that position. If a mutation exists on two out of three segments it will have an expected mutation allele frequency of about 2/3, as opposed to 1/3 if the mutation was on the unamplified segment. This is visualized in Figure 5 where there are two distinct bands when point mutation allele frequencies are plotted against their position on the chromosome.

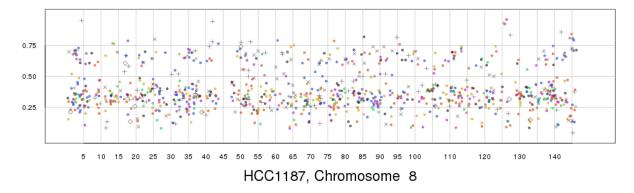

Figure 5: HCC1187, chromosome 8. The x-axis shows the position on the chromosome, the y-axis shows the mutation allele frequency. The whole chromosome has copy number three. Each point mutation with its corresponding mutation allele frequency is plotted against its position on the chromosome. Early mutations have a mutation allele frequency at approximately 0.66 or 0.33, and 0.33 for late mutations.

#### 2.3 Extract somatic mutations

To identify somatic point mutations in the tumour cells, tumor DNA was compared to patient-matched normal DNA. All variations from the reference genome that were not also found in the normal DNA were classified as potential somatic mutations. Complete Genomics gives every somatic mutation a so-called somatic score, that ranks each somatic mutation by quality. A score higher than -10 was considered as a real somatic mutation, all these were extracted from the data.

# 2.4 Filtering

It is the random occurrence of point mutations that make it feasible to use this approach in determining the TTD. When plotting each mutation allele frequency to its corresponding position on the chromosome, most of the point mutations were evenly distributed along the chromosome. Some regions had large clusters of point mutations very near each other, indicating a deviation in mutation exposure. These regions stood out from the rest and introduced a large source of error. To determine the TTD as accurate as possible, the small region filter and the normalized coverage filter were used.

#### 2.4.1 Small region filter

Longer regions produce more accurate TTD due to the greater amount of point mutations, while shorter tend to do the opposite. The data contained small regions that both split larger regions into smaller ones and contained too few point mutations to be reliable. Therefore regions shorter than two million base pairs and their point mutations were removed (Figure 6), and the adjacent larger regions with the same copy number were merged (Table 2 and Table 3).

Table 2: Unfiltered copy number region table. Showing a 100 kb long region that breaks a large segment.

I	HCC1187, chromosome 2							
Cn	Start	Stop	Length					
3	10000	5700000	5.69e6					
4	5700000	5800000	1.00e5					
3	5800000	10200000	4.40e6					

Table 3: Filtered copy number region table. Showing the extended segment.

HCC1187, chromosome 2						
Cn	Start	$\mathbf{Stop}$	Length			
3	10000	10200000	1.02e7			

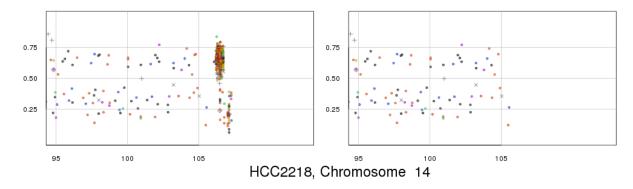

Figure 6: HCC2218, chromosome 14. The x-axis shows the position on the chromosome, the y-axis shows the mutation allele frequency. Some regions had a dense cluster of point mutations, these were a source of error. With the removal of short regions, the dense point mutation clusters were also removed. *Left*: A large accumulation of point mutations at the end of chromosome 14. *Right*: Point mutations after the removal of short regions.

#### 2.4.2 Normalized coverage filter

The normal genome contains very short regions where the copy number deviates from two. These will remain in the cancer genome. As Patchwork uses the tumour-normal coverage ratio, they appear to have the same copy number as the surrounding region. This contributed to a source of error when a small part of a segment contained the wrong copy number and would have been exposed differently to somatic mutations. A higher copy number correspond to a higher coverage, resulting that regions with different copy numbers than the majority in the segment stood out when comparing their coverages. Point mutations within those regions were removed (Figure 7).

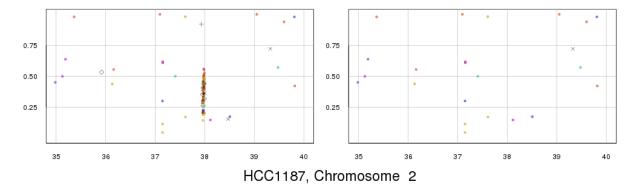

Figure 7: HCC1187, chromosome 2. The x-axis shows the position on the chromosome, the y-axis shows the mutation allele frequency. *Left*: A cluster of point mutations within a region with a different copy number than the surrounding ones. *Right*: Every mutation within the region is removed by the normalized coverage filter.

# 2.5 Histogram

The time to subclonal initiation is the time between  $t_1$  and  $t_2$  in Figure 1, that is the time the cell that eventually grew into a subclone took to gain another rate limiting mutation. The time is relative to the interval  $t_0$  until  $t_1$ . The ratio between number of point mutations accumulated during the subclone and the primary clone development (Equation 3) was used to estimate the time to subclonal initiation. The point mutations that were acquired during the primary clone development were inherited by all cells in the tumour.

In genomic segments where no copy number variations have occurred, point mutations would only affect one of the two chromosomes, resulting in a mutation frequency of around one half. Point mutations that occurred in the cell that grew into a subclone were present at a lower mutation allele frequency than the point mutations present in all cells. Because we did not measure the mutation allele frequency exactly, these point mutations would give rise to a distribution with a lower mutation allele frequency than the point mutations present in all tumour cells. From the bimodal distribution in the histogram of the mutation allele frequencies in Figure 8, the number of mutations in the two distributions was estimated by mirroring the side of the distribution that was facing outwards, reducing the overlap between the two as much as possible.

$$time\ until\ subclone\ initiation\ = \frac{\#subclonePointMutations}{\#pointMutationsInAllCells} \tag{3}$$

The proportion of subclone cells at the time of analysis were obtained by using the mutation allele frequency at the peak of the subclone distribution (Equation 4). A greater proportion of subclone increases the expected mutation allele frequency for subclonal point mutations, until the maximum value of one half is reached.

$$\%subclone = \frac{peakSubclone}{0.5} \tag{4}$$

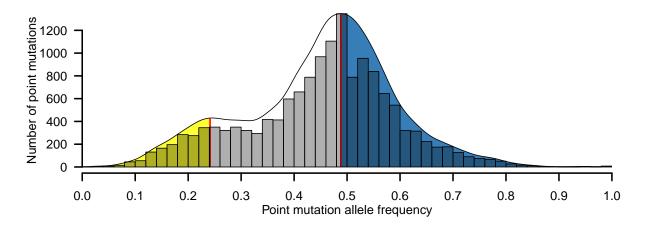

Figure 8: Histogram of the mutation allele frequencies in regions without copy number alterations in HCC2218. The red lines indicate mutation allele frequency peaks, the left peak is the subclone's peak and the right is the primary clone's peak. The subclone's peak is located at 0.242 and the primary clone's peak is 0.486. Using Equation 4 results in a subclone content of around 50%. The yellow and blue areas were used when calculating the number of point mutation in each clone. The number of point mutations under each color were doubled to estimate the opposite side of the distribution to minimize the interference between the two distributions.

### 2.6 Estimation of the time $t_0$ until $t_1$ in years

The time  $t_0$  until  $t_1$  for each sample was translated into years using the number of point mutations per megabase pairs (Mbp) divided by the point mutation rate per Mbp per year.

The point mutation rate in the exome in colon cancer is estimated to  $7.6 * 10^{-10}$  mutations per base pair per cell cycle, and a colon cancer cell's self-renewal rate is estimated to one per week<sup>9</sup>. The point mutation rate is higher in the genome compared to the exome due to purifying selection. In our primary colon cancer samples there was a 36.3% higher mutation rate in the genome compared to the exome. This was compensated by increasing the exome point mutation rate with 36.3%. Using Equation 5 the point mutation rate per Mbp per year was 0.0539.

To identify the number of point mutations per Mbp in each sample, segments from copy number one and two were used. The number of point mutations for each copy numbers were extracted using the same technique used in Section 2.5, subclonal mutations were excluded. Point mutations with extreme coverage were also excluded using the normalized coverage filter discussed in section 2.4.2. The number of point mutations is proportional to the copy number. This effect was compensated for. Using Equation 6 and 7 the time for each sample was calculated.

number of point mutations per Mbp per year = point mutation rate  $*1.363*52*10^6$ (5)

number of point mutations per Mbp = 
$$\frac{\text{number of point mutations}}{\text{segment lengths} * 10^6}$$
 (6)

$$year = \frac{\text{number of point mutations per Mbp}}{\text{number of point mutations per Mbp per year}}$$
 (7)

# 2.7 Application to real sequence data

The complexity of the genome in the samples A01\_167, C01\_203 and G01\_278 made the copy number analysis unfeasible and therefore they were not used. Table 4 shows the samples' time between  $t_0$  until  $t_1$ , the time to duplication, and the subclone content. Figure 9 visualizes the TTD for each sample. It shows three different scenarios, in HCC1187 the majority of copy number alterations appear to have happened halfway through, in HCC2218 TTDs are more evenly spread out in the interval and in E01 the greater part of the events happened relative late.

Table 4: Each samples' point mutations per mega base pairs (translated into years between the parentheses), time to subclone initiation (translated into years between the parentheses) and the subclone percentage.

Sample	MutPerMb ( $t_0$ to $t_1$ )	TTSI	$\operatorname{Subclone}(\%)$
HCC1187	1.48 (37.6 Yr)	0.09 (5.3 Yr)	37
HCC2218	2.2 (55.6  Yr)	0.17 (14.5  Yr)	50
E01	1.83 (46.4  Yr)	0.06 (4.2  Yr)	37

# 2.8 Point mutations present in genes with loss of heterozygozity

According to the "two hit hypothesis", one or many point mutations in tumour suppressor genes may have been involved in the disabling of the gene. Therefore, the point mutations in known tumour suppressor genes<sup>8</sup> who had lost either one of their alleles and contained at least one point mutation in an exon were extracted. In regions with greater copy numbers than one it was possible to determine if the point mutation occurred before or after the first duplication by using the same technique discussed in section 2.1. See appendix A for a complete list of the point mutations that were found.

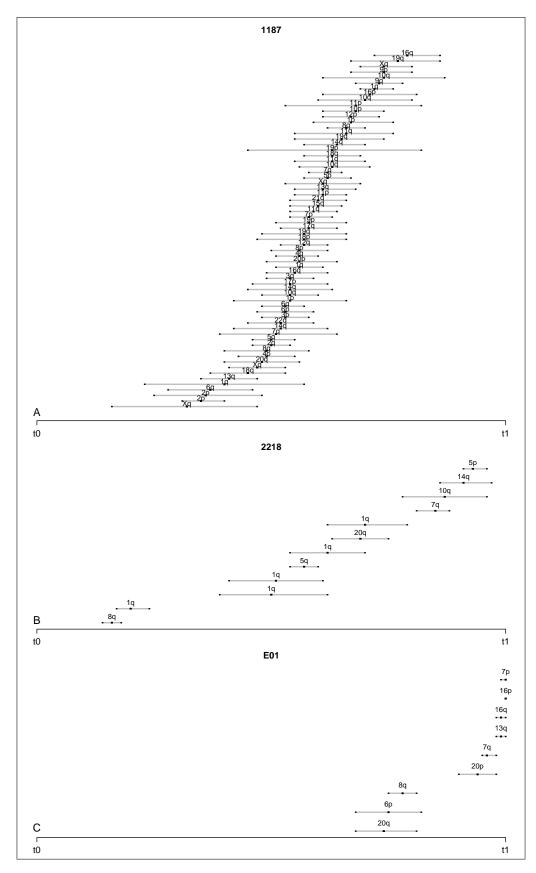

Figure 9: Illustration of TTDs with a 95% confidence interval. The label on top of the TTD is the chromosome position of each region. A:HCC1187, B: HCC2218 and C: E01.

## 3 Discussion and conclusion

I have developed a bioinformatic method that can be used to increase the knowledge about cancer and cancer development. We only had access to two breast cancer cell lines and one primary colon cancer sample, this made it difficult to draw conclusions about recurrent patterns. This will be interesting when more primary colon cancer samples are analyzed. Different subgroups of colon cancer may have distinct developmental patterns, were different regions gets amplified at different stages. Combining the TTD, the time between  $t_0$  and  $t_1$ , time to subclonal initiation and the subclone content gives us new ways to describe tumour development. These parameters can also be used to improve methods for allele specific copy number estimation like Patchwork. This method can also be used with junction information in further development of digital karyotyping, to be able to have access to the karyotype of a sample just from its sequence instead of using spectral karyotyping, where the chromosomes are coloured with florescence and is quantified with a light microscope. The digital karyotype gives a more complete picture of the actual karyotype compared with what can be achieved with a light microscope.

I encountered many obstacles during the course of the project that needed to be resolved. The non-random distribution of point mutations was by far the largest problem, but due to the success of the two filters the analysis was feasible.

Greenman *et al.*'s method is significantly more advance and is used on smaller regions. That method requires a very high sequence coverage. Therefore that method is not applicable for validation of our results<sup>7</sup>.

Limitations: The method that we used to estimate the number of point mutations from the mutation allele frequency distributions in Section 2.5 is rough but good enough compared to other methods such as Mixture Models, which are more accurate but is more difficult to automate.

Non-synonymous somatic mutations in the exome affect the resulting translated protein, which in some cases will remove its function and reduce the specific growth rate of the cell. The result is a lower observed mutation rate in the exome. The difference varies between individual tumours but is consistently higher in the whole genome compared to the exome. Vogelstein  $et\ al.$  used exome data to identify the point mutation frequency per self-renewal. By combining these two pieces of information we can estimate the time  $t_0$ - $t_2$  in years. To get a more accurate estimate it would be better if the mutation rate per nucleotide per cell division was estimated directly from the whole genome.

Conclusion: This method builds upon recent technological advances in bioinformatics and whole genome sequence data to provide new insights into cancer development. We are looking forward to analyzing new whole genome sequenced colon cancer samples. With more data sets available, our method will provide a more detailed view of copy number alterations in cancer. This will lead to a greater understanding how cancer evolves and might find differences between different types of colon cancer.

# 4 Acknowledgements

I would like to thank my supervisor Anders Isaksson, who gave me the opportunity to work in his group and help me with the project, Markus Mayrhofer for the genetic expertise, Christofer Bäcklin for R support, Martin Dahlö for UPPMAX support and Sebastian DiLorenzo and Hanna Göransson Kultima for brainstorming with me.
