The exclusive process $e^+ e^- \rightarrow \Lambda \bar{\Lambda}$, with $\Lambda \rightarrow p \pi^-$ and $\bar{\Lambda} \rightarrow \bar{p} \pi^+$, has been studied at $\sqrt{s} = 2.396$ GeV for measurement of the timelike electric and magnetic form factors, $G_E$ and $G_M$. A data sample, corresponding to an integrated luminosity of 66.9 pb$^{-1}$, was collected with the BESIII detector for this purpose. A multidimensional analysis with a complete decomposition of the spin structure of the reaction enables a determination of the modulus of the ratio $R = |G_E/G_M|$ and, for the first time for any baryon, the relative phase $\Delta \Phi = \Phi_E - \Phi_M$. The resulting values are $R = 0.96 \pm 0.14\text{(stat)} \pm 0.02\text{(syst)}$ and $\Delta \Phi = 37^\circ \pm 12^\circ\text{(stat)} \pm 6^\circ\text{(syst)}$, respectively. These are obtained using the recently established and most precise value of the asymmetry parameter $\alpha_s = 0.750 \pm 0.010$ measured by BESIII. In addition, the cross section is measured with unprecedented precision to be $\sigma = 118.7 \pm 5.3\text{(stat)} \pm 5.1\text{(syst)}$ pb, which corresponds to an effective form factor of $|G| = 0.123 \pm 0.003\text{(stat)} \pm 0.003\text{(syst)}$. The contribution from two-photon exchange is found to be negligible. Our result enables the first complete determination of baryon timelike electromagnetic form factors.

One of the most challenging questions in contemporary physics is to understand the strong interaction in the confinement domain, i.e., where quarks form hadrons. This puzzle manifests itself in one of the most abundant building blocks of the Universe: the nucleon. Neither its size [1], its spin [2], nor its intrinsic structure [3] is fully understood. The latter has been extracted from spacelike electromagnetic form factors (EMFFs), fundamental properties of hadrons that have been studied since the 1960s [4]. In particular, the neutron charge distribution is intriguing [3]. Hyperons provide a new angle on the nucleon puzzle:

What happens if we replace one of the $u$ and $d$ quarks with a heavier $s$ quark? A systematic comparison of octet baryons sheds light on to what extent $SU(3)$ flavor symmetry is broken. The importance of hyperon structure was pointed out as early as 1960 [5], but has not been subjected to rigorous experimental studies until now. The main reason is that spacelike EMFFs of hyperons are not straightforward to access experimentally since their finite lifetime makes them unsuitable as beams and targets. Instead, the electromagnetic structure can be quantified in terms of timelike form factors. These can be accessed in, e.g., hyperon-antihyperon production in $e^+ e^- \rightarrow \gamma^* \rightarrow Y\bar{Y}$, where $Y$ denotes the hyperon. The experimentally accessible timelike form factors are related to more intuitive spacelike quantities such as charge and magnetization densities by dispersion relations [6].

Spin 1/2 baryons are described by two independent EMFFs, commonly the electric form factor $G_E$ and the
magnetic form factor $G_M$. These are functions of the four-momentum transfer squared, $s = q^2$: $G_E \equiv G_E(s)$ and $G_M \equiv G_M(s)$. As a consequence of the optical theorem, timelike EMFFs above the two-pion threshold $s \gtrsim 4m^2$ have a nonzero imaginary part. This means that if $G_E$ and $G_M$ are different, they have a nonzero relative phase $[7,8]$. This phase, $\Delta \Phi \equiv \Delta \Phi(s)$, must be zero at the kinematic threshold, where by definition the electric and the magnetic form factors are equal.

The asymptotic behavior of the timelike EMFFs as $s \to \infty$ can be obtained from the corresponding spacelike region as a consequence of the Pphragmén-Lindelöf theorem $[9]$. Since in the spacelike region, EMFFs are real, the same must be true for the timelike region in the $s \to \infty$ limit. This means that the phase tends to integer multiples of $\pi$ radians, depending on the $s$ power-law behavior $[10,11]$ and the eventual presence of spacelike zeros $[8]$. However, for intermediate $s$ the phase can have any value. This would introduce polarization effects on the final state, even if the initial state is unpolarized $[7]$. Thanks to the weak, parity violating decays of hyperons, the polarization is experimentally accessible. This provides unique opportunities compared to nucleons.

The recent development of high-intensity electron-positron colliders in the strange and charm energy region offers new possibilities for detailed structure studies of hyperons. The first measurement of $e^+e^- \to \Lambda\bar{\Lambda}$ production was reported by the DM2 Collaboration $[12]$. The first determination of the $\Lambda$ EMFFs was provided by the BABAR Collaboration, using the initial state radiation (ISR) method $[13]$. However, the sample was insufficient for a clear separation of the electric and magnetic form factors. An attempt was made to extract the phase from the $\Lambda$ polarization, but the result was inconclusive $[13]$. The cross section of the production of protons and ground-state hyperons in $e^+e^-$ annihilations at $\sqrt{s} = 3.69, 3.77$, and 4.17 GeV was measured with CLEO-c data. The magnetic form factors were extracted assuming $|G_E| = |G_M|$ $[14]$. The BESIII Collaboration performed in 2011–2012 an energy scan, enabling an investigation of the $\Lambda$ production cross section at four energies between $\sqrt{s} = 2.23$ and $\sqrt{s} = 3.08$ GeV. An unexpected enhancement at the kinematic threshold was observed $[15]$. At higher energies, the statistical precision was improved compared to previous experiments, though still not sufficient to extract the form factor ratio $R \equiv |G_E/G_M|$. The recent experimental progress has resulted in an increasing interest from the theory community. For instance, predictions of the relative phase have been made, based on various $\Lambda\bar{\Lambda}$ potential models $[16]$ with input data from the PS185 experiment $[17]$.

In this Letter, the exclusive process $e^+e^- \to \Lambda\bar{\Lambda}$ ($\Lambda \to p\pi^-$, $\bar{\Lambda} \to \bar{p}\pi^+$) is studied at $\sqrt{s} = 2.396$ GeV. This energy gives the optimal $\Lambda\bar{\Lambda}$ detection rate—at larger energies, the cross section becomes too small $[13]$, and at lower energies, the reconstruction efficiency goes down rapidly. The latter is due to the pions from the $\Lambda$ decays that have too low momenta to reach the detectors $[15]$. In the following, we present our measurements of the cross section $\sigma \equiv \sigma(s)$, the ratio $R = |G_E/G_M|$, and, for the first time, the relative phase $\Delta \Phi$.

Assuming one-photon exchange ($e^+e^- \to \gamma^* \to \bar{B}B$), the Born cross section of spin $1/2$ baryon-antibaryon pair production can be parametrized in terms of $G_E$ and $G_M$:

$$
\sigma_{\bar{B}B}(s) = \frac{4\pi\alpha^2\beta}{3s} \left( |G_M(s)|^2 + \frac{1}{2\tau} |G_E(s)|^2 \right).
$$

Here, $\alpha = 1/137.036$ is the fine-structure constant, $\beta = \sqrt{1 - 4m_B^2/s}$ the velocity of the produced baryon, $m_B$ the mass of the baryon, and $\tau = s/(4m_B^2)$.

In most previous experiments, where the small data samples did not allow for a separation between $G_E$ and $G_M$, the effective form factor has been studied. It is defined as

$$
|G(s)| \equiv \sqrt{\frac{\sigma_{\bar{B}B}(s)}{1 + \frac{4\pi\alpha^2\beta}{3s}}},
$$

and gives a quantitative indication of the deviation from the pointlike cross section.

A complete decomposition of the complex $G_E$ and $G_M$ requires a multidimensional analysis of the reaction and the subsequent baryon decays. In Refs. $[18,19]$, the joint decay distribution of $e^+e^- \to \Lambda\bar{\Lambda}(\Lambda \to p\pi^-, \bar{\Lambda} \to \bar{p}\pi^+)$ was derived in terms of the phase $\Delta \Phi$ and the angular distribution parameter $\eta = (\tau - R^2)/(\tau + R^2)$:

$$
\mathcal{W}(\xi) = T_0 + \eta T_5 - \alpha_\Lambda^2 \left[ T_1 + \sqrt{1 - \eta^2 \cos(\Delta \Phi)} T_2 + \eta T_6 \right] + \alpha_\Lambda \sqrt{1 - \eta^2} \sin(\Delta \Phi)(T_3 - T_4),
$$

where $\alpha_\Lambda$ denotes the decay asymmetry of the $\Lambda \to p\pi^-$ decay. The seven functions $T_k(\xi)$ do not depend on the parameters $\eta$ and $\Delta \Phi$, but only on the measured angles:

$$
T_0(\xi) = 1,
T_1(\xi) = \sin^2\theta \sin\theta_1 \sin\theta_2 \cos\phi_1 \cos\phi_2 + \cos^2\theta \cos\theta_1 \cos\theta_2,
T_2(\xi) = \sin\theta \cos\theta (\sin\theta_1 \cos\theta_2 \cos\phi_1 + \cos\theta_1 \sin\theta_2 \cos\phi_2),
T_3(\xi) = \sin\theta \cos\theta \sin\theta_1 \sin\phi_1,
T_4(\xi) = \sin\theta \cos\theta \sin\theta_2 \sin\phi_2,
T_5(\xi) = \cos^2\theta,
T_6(\xi) = \cos\theta_1 \cos\theta_2 - \sin^2\theta \sin\theta_1 \sin\theta_2 \sin\phi_1 \sin\phi_2.
$$

The five angles measured are the $\Lambda$ scattering angle $\theta$ with respect to the electron beam, the proton helicity angles $\theta_1$ and $\phi_1$ from the $\Lambda \to p\pi^-$ decay, and the antiproton...
Using a GEANT-based Monte Carlo (MC) simulation, the asymmetry parameter $\alpha$ measured by the BESIII Collaboration to be $4.750 \pm 0.010$ [20]. This value has been adopted by the Particle Data Group [21]. The mass window from the Particle Data Group [21]. The mass window corresponds to $+\Delta m$ of $|M(p\pi^-/\pi^+)|$ mass resolution.

The detection of the coordinate system used to describe the $e^+e^- \rightarrow \Lambda\bar{\Lambda}$ ($\Lambda \rightarrow p\pi^-$, $\bar{\Lambda} \rightarrow \bar{p}\pi^+$) process.

The term $T_0 + \eta T_6$ in Eq. (3) describes the scattering angle distribution of the $\Lambda$ hyperon. The term $a_\Lambda \sqrt{1 - \eta^2} \sin(\Delta \Phi)(T_3 - T_4)$ accounts for the transverse polarization $P_y$ of the $\Lambda$ and $\bar{\Lambda}$. In particular, the $\Lambda$ transverse polarization $P_y$ is given by

$$P_y = \sqrt{1 - \eta^2} \sin \theta \cos \theta \sin(\Delta \Phi).$$

Finally, the $\alpha_\Lambda [T_1 + \sqrt{1 - \eta^2} \cos(\Delta \Phi)T_2 + \eta T_6]$ term describes the spin correlations between the two hyperons.

The asymmetry parameter $a_\Lambda$ has recently been measured by the BESIII Collaboration to be $a_\Lambda = 0.4750 \pm 0.010$ [20]. This value has been adopted by the Particle Data Group in the 2019 update of Ref. [21].

A data sample corresponding to an integrated luminosity of 66.9 pb$^{-1}$ was collected with the Beijing spectrometer (BESIII) at the Beijing Electron Positron Collider (BEPCII). The BESIII detector has a geometrical acceptance of 93% of the solid angle. BESIII contains a small-cell, helium-based main drift chamber (MDC), a time-of-flight system based on plastic scintillators, an electromagnetic calorimeter made of CsI(Tl) crystals, a muon counter made of resistive plate chambers, and a superconducting solenoid magnet with a central field of 1.0 T. A detailed description of the detector and its performance can be found in Ref. [22].

The particle propagation through the detector is modeled using a GEANT-based Monte Carlo (MC) simulation software package, Boost [24]. The multidimensional analysis for determination of $R$ and $\Delta \Phi$ enables a model-independent efficiency correction. The simulations for this purpose are performed with a MC sample generated by a phase space generator. The determination of $\sigma$ and $G$ was found to be more precise using an approach with a global efficiency. The latter was obtained from simulations of $e^+e^- \rightarrow \Lambda\bar{\Lambda}$ ($\Lambda \rightarrow p\pi^-$, $\bar{\Lambda} \rightarrow \bar{p}\pi^+$) using the measured values of $|G_E/G_M|$ as input to the CONEXC generator [25]. In CONEXC, higher order processes with one radiative photon are taken into account. For background studies, an inclusive MC sample of continuum processes $e^+e^- \rightarrow q\bar{q}$ with $q = u, d, s$ is used.

In the analysis, events are reconstructed by the final state particles $p, \pi^-, \bar{p}$, and $\pi^+$. We therefore require at least four charged tracks per event. Each track must be reconstructed within the MDC, i.e., with polar angles $|\cos \theta| < 0.93$, measured in the laboratory frame between the direction of the track and the direction of the $e^+$ beam. The momentum of each track must be smaller than 0.5 GeV/c. It was found in simulations that the momentum distributions of pions and protons or antiprotons are well separated due to kinematics. Therefore, we can identify tracks with momenta smaller than 0.2 GeV/c as $\pi^+/\pi^-$ candidates, whereas tracks with momenta larger than 0.2 GeV/c are identified as $p/\bar{p}$ candidates. This was found to give an optimal signal-to-background ratio and the results are consistent with those obtained using standard particle identification criteria.

The $\Lambda$ and $\bar{\Lambda}$ candidates are reconstructed by fitting each $p\pi^-/\bar{p}\pi^+$ to a common vertex corresponding to the decay of $\Lambda$ ($\bar{\Lambda}$). A four-constraint (4C) kinematic fit is applied on the $\Lambda$ and $\bar{\Lambda}$ candidates, using energy and momentum conservation in $e^+e^- \rightarrow \Lambda\bar{\Lambda}$ and requiring $\chi^2_{4C} < 50$. We require the $p\pi^-/\bar{p}\pi^+$ invariant mass to fulfill $|M(p\pi^-/\bar{p}\pi^+) - m_\Lambda| < 6$ MeV/c$^2$. The $M(p\pi^-)$ distribution is shown in Fig. 2. Here, $m_\Lambda$ is the nominal mass of $\Lambda$ from the Particle Data Group [21]. The mass window corresponds to $\pm 4\sigma$ of $|M(p\pi^-/\bar{p}\pi^+)|$ mass resolution.

FIG. 1. Definition of the coordinate system used to describe the $e^+e^- \rightarrow \Lambda\bar{\Lambda}$ ($\Lambda \rightarrow p\pi^-$, $\bar{\Lambda} \rightarrow \bar{p}\pi^+$) process.

![Invariant mass distribution of $p\pi^-$](image2)

FIG. 2. The invariant mass of $p\pi^-$ for BESIII data (black dots) and Monte Carlo data (red line) fulfilling all selection criteria except those on invariant mass. The MC data are normalized to the total number of events in the data.
After applying all event selection criteria, 555 event candidates remain in our data sample.

The background channels are identified by performing inclusive $q\bar{q}$ simulations. The main contribution are events from $\Delta^+\bar{p}n^- (\Delta^- p\pi^+)$ and nonresonant $p\bar{p}\pi^+\pi^-$ production, i.e., reactions with similar topology as $e^+e^- \rightarrow \Lambda\bar{\Lambda}$ ($\Lambda \rightarrow p\pi^-$, $\bar{\Lambda} \rightarrow \bar{p}\pi^+$). The contamination is found to be on the percent level. A two-dimensional sideband study provides an independent, data-driven method to quantify the background contribution from events with misidentified $\Lambda/\bar{\Lambda}$. The $\Lambda/\bar{\Lambda}$ sideband regions are defined within $1.097 < M(p\pi^-/\bar{p}\pi^+) < 1.109$ GeV/$c^2$ and $1.123 < M(p\pi^-/\bar{p}\pi^+) < 1.135$ GeV/$c^2$ for events with a $\Lambda/\bar{\Lambda}$ candidate. The number of background events is determined to be $14 \pm 4$, corresponding to a background level of 2.5%.

In our analysis, we extract the parameters $\eta$ and $\Delta\Phi$ by applying a multidimensional event-by-event maximum log-likelihood fit in MINUIT [26]. The multidimensional approach takes the reconstruction efficiency into account in a model-independent way. The results from the fit are $\eta = 0.12 \pm 0.14$, giving $R = 0.96 \pm 0.14$, and $\Delta\Phi = 37^\circ \pm 12^\circ$, where the uncertainties are statistical. The correlation coefficient between $\eta$ and $\Delta\Phi$ is 0.17. The $\Lambda$ angular distribution and the polarization, multiplied with the constant $\alpha_{1\Lambda}$, as a function of the scattering angle are shown in Fig. 3. The characteristic dependence of the polarization on $\cos \theta$ is a consequence of the nonzero phase.

A thorough investigation of possible sources of systematic uncertainties has been performed. The uncertainties from the luminosity measurement, tracking, and background are found to be negligible. The non-negligible contributions from the angular fit range (for $R$), from requirements on $\chi^2_{AC}$ (for $\Delta\Phi$), and requirements on the invariant mass are summarized in Table I. The total systematic uncertainty is about 7 times smaller than the statistical for $R$ and about 2 times smaller for $\Delta\Phi$.

The formalism presented in Eq. (3) assumes the one-photon exchange to be dominant in the production mechanism. A significant contribution of two-photon exchange of the lowest order results in an additional term $\kappa \cos \theta \sin^2 \theta$ in Eq. (3) due to interference of the one- and two-photon amplitudes [27]. This would give rise to a nonzero asymmetry in the $\Lambda$ angular distribution [28]:

$$A = \frac{N(\cos \theta > 0) - N(\cos \theta < 0)}{N(\cos \theta > 0) + N(\cos \theta < 0)},$$

where $A$ is related to $\kappa$ according to

$$A = \frac{3 \kappa}{43 + \eta}.$$

In this work, the asymmetry is measured to be $A = 0.001 \pm 0.037$ and indicates a negligible contribution from two-photon exchange with respect to the statistical precision.

The total cross section has been calculated using
\[
\sigma_{\Lambda\bar{\Lambda}} = \frac{N_{\text{signal}}}{L_\text{int}e(1 + \delta)B},
\]
(7)
where \(N_{\text{signal}} = N_{\text{data}} - N_{\text{bg}}\), \(N_{\text{data}} = 555\) is the number of events in the sample after all selection criteria, \(N_{\text{bg}} = 14 \pm 4\) the number of events in the sidebands, \(L_\text{int}\) the integrated luminosity, and \(e\) the global efficiency. The radiative correction factor \(1 + \delta\) is determined taking ISR and vacuum polarization into account. The factor \(B\) is the product of the branching fractions of \(\Lambda \rightarrow p\pi^−\) and \(\bar{\Lambda} \rightarrow \bar{p}\pi^+,\) taken from Ref. [21].

The following systematic effects contribute to the uncertainty of the cross section measurement. (i) The uncertainty from the \(\Lambda\) and \(\bar{\Lambda}\) reconstruction is determined to be 1.1% and 2.4%, respectively, using single-tag samples of \(\Lambda\) and \(\bar{\Lambda}\). (ii) The kinematic fit contributes with 1.7%. (iii) The model dependence of the global efficiency is evaluated by changing the input \(R\) with one standard deviation \((\pm0.14)\) in the CONEXC generator. This gives an uncertainty of 2.8%. The phase \(\Delta \Phi\) was found to have a negligible impact on the efficiency. (iv) The uncertainty of the integrated luminosity is 1.0% [29]. The individual uncertainties are assumed to be uncorrelated and are therefore added in quadrature, which yields a total systematic uncertainty of the cross section of 4.3%. The systematic uncertainty in the effective form factor \(|G|\) is obtained using error propagation.

In summary, the process \(e^+e^- \rightarrow \Lambda\bar{\Lambda} (\Lambda \rightarrow p\pi^-\), \(\bar{\Lambda} \rightarrow \bar{p}\pi^+)\) is studied with 66.9 pb\(^{-1}\) of data collected at 2.396 GeV. The cross section and the effective form factor are obtained to be \(\sigma = 118.7\pm5.3\) (stat)\(\pm5.1\) (syst) pb and \(|G| = 0.123\pm0.003\) (stat)\(\pm0.003\) (syst). The effective form factor is about one half of that of the proton at the corresponding excess energy [30]. The ratio \(R = |G_E/G_M|\) is determined with unprecedented precision to be \(R = 0.96 \pm 0.14\) (stat)\(\pm0.02\) (syst). The relative phase between \(G_E\) and \(G_M\) is determined for the first time to be \(\Delta \Phi = 37^\circ \pm 12^\circ\) (stat)\(\pm6^\circ\) (syst).

The nonzero value of the relative phase implies that the imaginary part of the electric and the magnetic form factors is different. Equivalently, this means that not only the \(s\)-wave but also the \(d\)-wave amplitude contribute to the production and their interference results in a polarized final state.

This first complete hyperon EMFF measurement is a milestone in the study of hyperon structure, where the long-term goal is to describe charge and magnetization densities for hyperons in the same way as for nucleons [3]. In order to achieve this, similar measurements must be carried out at several energies. For nucleons, the scale at which spacelike EMFFs approach the timelike EMFFs is straightforward to extract since both spacelike and timelike EMFFs are experimentally accessible. For hyperons, for which only the timelike EMFFs can be measured, the corresponding scale can instead be obtained where the phase approaches a constant value that is an integer multiple of \(\pi\). For this purpose, the methods developed for this study can be applied at other energies, provided the data sample at each energy is large enough.

In addition, this measurement offers a unique and clean opportunity to learn about the \(\Lambda\bar{\Lambda}\) interaction close to threshold. In a recent theory paper [16], predictions have been made using final state interaction (FSI) potentials. The latter were obtained from fits to PS185 data from the \(\bar{p}p \rightarrow \Lambda\bar{\Lambda}\) reaction [17]. While the sensitivity of the energy dependence of the effective form factor \(|G|\) to the \(\Lambda\bar{\Lambda}\) FSI potential is very small, the predictions of \(R\) and, even more, \(\Delta \Phi\) depend significantly on the FSI potential. Our measurement slightly favors the model I or model II potential of Ref. [31]. This illustrates the sensitivity of our data to the \(\Lambda\bar{\Lambda}\) interaction.
