Assessment of the validity of the measurement of newborn and maternal health-care coverage in hospitals (EN-BIRTH): an observational study

Summary

Background Progress in reducing maternal and neonatal baby deaths and stillbirths is impeded by data gaps, especially regarding coverage and quality of care in hospitals. We aimed to assess the validity of indicators of maternal and newborn health-care coverage around the time of birth in survey data and routine facility register data.

Methods Every Newborn-BIRTH Indicators Research Tracking in Hospitals was an observational study in five hospitals in Bangladesh, Nepal, and Tanzania. We included women and their newborn babies who consented on admission to hospital. Exclusion criteria at admission were no fetal heartbeat heard or imminent birth. For coverage of uterotonic to prevent post-partum haemorrhage, early initiation of breastfeeding (within 1 h), neonatal bag-mask ventilation, kangaroo mother care (KMC), and antibiotics for clinically defined neonatal infection (sepsis, pneumonia, or meningitis), we collected time-stamped, direct observation or case note verification data as gold standard. We compared data reported via hospital exit surveys and via hospital registers to the gold standard, pooled using random effects meta-analysis. We calculated population-level validity ratios (measured coverage to observed coverage) plus individual-level validity metrics.

Findings We observed 23 471 births and 840 mother–baby KMC pairs, and verified the case notes of 1015 admitted newborn babies regarding antibiotic treatment. Exit-survey-reported coverage for KMC was 99·9% (95% CI 98·3–100) compared with observed coverage of 100% (99·9–100), but exit surveys underestimated coverage for uterotonic (84·7% [79·1–89·5] vs 99·4% [98·7–99·8] observed), bag-mask ventilation (0·8% [0·4–1·4] vs 4·4% [1·9–8·1] observed), and antibiotics for neonatal infection (74·7% [55·3–90·1] vs 96·4% [94·0–98·6] observed). Early breastfeeding coverage was overestimated in exit surveys (53·2% [39·4–66·8] vs 10·9% [3·8–21·0] observed). “Don’t know” responses concerning clinical interventions were more common in the exit survey after caesarean birth. Register data underestimated coverage of uterotonics (77·9% [37·8–99·5] vs 99·2% [98·6–99·7] observed), bag-mask ventilation (4·3% [2·1–7·3] vs 5·1% [2·0–9·6] observed), KMC (92·9% [84·2–98·5] vs 100% [99·9–100] observed), and overestimated early breastfeeding (85·9% [58·1–99·6] vs 12·5% [4·6–23·6] observed). Inter-hospital heterogeneity was higher for register-recorded coverage than for exit survey report. Even with the same register design, accuracy varied between hospitals.

Interpretation Coverage indicators for newborn and maternal health care in exit surveys had low accuracy for specific clinical interventions, except for self-report of KMC, which had high sensitivity after admission to a KMC ward or corner and could be considered for further assessment. Hospital register design and completion are less standardised than surveys, resulting in variable data quality, with good validity for the best performing sites. Because approximately 80% of births worldwide take place in facilities, standardising register design and information systems has the potential to sustainably improve the quality of data on care at birth.

Introduction Investment in global health measurement has particularly focused on outcomes, notably deaths. Accurate data are urgently needed to track the progress towards the Sustainable Development Goals (SDGs) to end the annual 5·1 million preventable stillbirths and newborn deaths, plus 0·3 million maternal deaths by 2030.1 Despite nearly 80% of births worldwide now being in health-care facilities,2 many avoidable deaths occur, notably intrapartum stillbirths and in preterm newborn babies.3,4 Many evidence-based, high-impact interventions for maternal and newborn health are
Research in context

Evidence before this study
Increasing coverage and quality of care around the time of birth is fundamental to reducing 5·3 million maternal, fetal, and newborn deaths and disability every year and achieving the Sustainable Development Goals. National and global tracking of maternal and newborn health has mostly used measures of contact coverage (eg, skilled birth attendance), with little attention paid to indicators of content or quality of care. We searched Ovid MEDLINE for articles published in English after Jan 1, 2010, with the search terms “valid” AND “maternal or newborn or neonate or labour or childbirth or delivery or intrapartum” AND “coverage or indicator or measure or track or numerator or denominator” and restricted to low-income and middle-income settings. Of the 598 papers identified, 17 met our inclusion criteria, among which most observational studies focused on indicator measurement validation in surveys with two for routine register data. We found no additional relevant documents in the grey literature. Previous studies have reported low validity for measures around the time of birth. High-priority newborn interventions, such as neonatal bag-mask ventilation and kangaroo mother care (KMC), have not undergone validity testing in surveys or register data. Early initiation of breastfeeding has only been validated in surveys. WHO and UNICEF’s Every Newborn Action Plan prioritised validation of data on indicators of maternal and newborn coverage of care to improve measurement of content of care and especially through routine data systems.

Added value of this study
The Every Newborn-Birth Indicators Research Tracking in Hospitals (EN-BIRTH) study was done to find five hospitals in Bangladesh, Nepal, and Tanzania, and aimed to assess the validity of data for five indicators of maternal and newborn health-care coverage in two data sources: routine facility registers and women’s report at exit survey. These data were compared against a gold standard of direct observation or case note verification. EN-BIRTH was about 10 times larger than previous facility-based validation studies and included more than 25,000 cases—either observed births or KMC or newborn admission case notes. This study is the first to assess the validity of routine register data for most of these indicators, and of survey data for the hospital newborn care indicators. We found that exit survey reports had low accuracy for uterotonic coverage and for early initiation of breastfeeding, consistent with previous smaller studies. Population-based household surveys already capture early initiation of breastfeeding coverage but research is needed to improve accuracy. We also found survey-reported data on bag-mask ventilation had low accuracy and neonatal infection treatment with antibiotics had low sensitivity among the target group. KMC coverage was accurately reported at exit survey by women who had practised KMC. Thus, further work is required to assess whether KMC report remains reliable after the typical household survey recall period of 2–5 years, and also to ascertain the extent to which mothers who did not practise KMC misreport having done so. Routine registers in some hospitals were found to be highly complete, but accuracy varied between hospitals, even with the same register design. Register accuracy for uterotonic was excellent in two hospitals, and KMC sensitivity was excellent in two hospitals and good in two hospitals. One hospital had good register accuracy for bag-mask ventilation. For early initiation of breastfeeding, register accuracy was poor in all four study hospitals with a register column.

Implications of all the available evidence
For care around the time of birth, surveys are important for estimating population-based contact coverage and family-led behaviours such as breastfeeding, but our findings do not support adding questions about clinical interventions to surveys, with the possible exception of admission for KMC. Given that approximately 80% of the world’s births are now in facilities, routine registers can provide data on intervention delivery more rapidly and at lower cost than surveys. Optimising register design, filling, and flow into national routine information systems requires investment in implementation research. Caesarean birth negatively affected the accuracy of survey data for the hospital newborn care indicators. We found that exit survey reports had low accuracy for uterotonic coverage and for early initiation of breastfeeding, consistent with previous smaller studies. Delivered in health-care facilities, yet gaps in quality of care and gaps in data result in missed opportunities. The SDGs aspire to achieve universal health coverage, which will be difficult without addressing the crucial measurement gaps regarding effective coverage and quality around the time of birth. Coverage is defined as the proportion of individuals receiving an intervention or practice (numerator) among the population in need of that intervention or practice (denominator). National and global tracking of coverage has primarily focused on survey measurement of contacts with the health system (eg, institutional birth), with few indicators capturing content (eg, interventions) or quality of care. Maternal and newborn coverage of care in low-income and middle-income countries (LMICs) is mainly tracked through large-scale population-based household surveys, notably the Demographic and Health Surveys (DHS) programme and UNICEF’s Multiple Indicator Cluster Surveys (MICS). Although these surveys importantly measure population-based contact coverage, previous research has found mixed validity for the content of care around the time of birth (eg, breastfeeding). DHS has done more than 400 surveys in 90 countries. With over 400 questions in the DHS core questionnaire,
focus has been on the need to validate additional questions before adding. Overall, few survey indicators have been validated, and those relating to clinical care for small and ill newborn babies, have not previously been validated.9

The shift to most births worldwide being in facilities, paired with rapid improvements for routine national health management information systems (HMIS) including digitalisation, have potential to transform measurement of coverage and quality of care for women and newborn babies, including in high-burden settings.7 Health workers document details of admitted women and newborn babies in routine facility registers, usually in parallel to individual patient case notes. These registers are the primary source for aggregate data that flow into routine HMIS. The quality of HMIS data, or mistrust of quality, impedes full use by policy makers.18–20

Validity testing of other core or additional indicators will be paired with rapid improvements for routine national health management information systems (HMIS) including digitalisation, have potential to transform measurement of coverage and quality of care for women and newborn babies, including in high-burden settings.7 Health workers document details of admitted women and newborn babies in routine facility registers, usually in parallel to individual patient case notes. These registers are the primary source for aggregate data that flow into routine HMIS. The quality of HMIS data, or mistrust of quality, impedes full use by policy makers.18–20

Previous studies of routine paper-based registers in facilities in LMICs have reported on data availability,12,22 but only two small observational studies have examined some aspects of register measurement validity for care around the time of birth.7,24

Transforming measurement and use of data to track coverage and quality of care is one of five strategic objectives in the Every Newborn Action Plan, led by WHO and UNICEF, implemented in more than 92 countries.25 Validation of coverage measurement for interventions and practices (content of care) was prioritised.26 Core indicators regarding high-impact maternal and newborn care recommended by WHO were selected as outlined in the measurement improvement roadmap for Every Newborn27,28 and Ending Preventable Maternal Mortality monitoring framework.27 The Every Newborn-Birth Indicators Research Tracking in Hospitals (EN-BIRTH) study was designed to address these evidence gaps by assessing measurement validity for high-priority indicators of newborn and maternal health coverage to inform their use in routine HMIS and population-based surveys for national and global tracking. None of these indicators had previously been validated in routine register data and few in survey data.26

Criterion validity testing compares measurement against an objective gold standard to assess whether indicators measure what they intend to, and can provide accurate evidence to inform programmes.29 The EN-BIRTH study protocol outlined four objectives: (1) to assess the validity of numerator measurement, (2) to compare denominators, (3) to evaluate content and quality of care, and (4) to assess barriers and enablers to routine register measurement.29 We report results on the EN-BIRTH study’s first objective for five prioritised core coverage indicators (appendix p 4). Validity testing of other core or additional indicators will be reported separately.

Methods

Study design and participants
EN-BIRTH was a mixed-methods observational study that compared directly observed or verified interventions and practices (considered to be the gold standard) with coverage measured by two different data sources: women’s report at exit survey after discharge and hospital routine register records (appendix p 5). The contexts and methods are detailed in a previously published protocol.28 Five public hospitals providing comprehensive emergency obstetric and neonatal care and including the interventions of interest in the contexts of high mortality burden in sub-Saharan Africa and south Asia were identified in Bangladesh, Nepal, and Tanzania (appendix p 6). Inclusion and exclusion criteria are given in the panel.

Participants gave voluntary informed written consent before recruitment for observation and again for exit surveys. This study was granted ethics approval by institutional review boards in all three countries and by the London School of Hygiene & Tropical Medicine, London, UK (appendix p 7). All collaborating partners have signed data sharing and transfer agreements.

Procedures

In each hospital, consenting participants were recruited in three service delivery contexts to collect data on five selected interventions (panel). Trained researchers in each hospital obtained informed consent and collected participant data prospectively. Data collection varied by site from 7 months to 12 months to achieve the required precision-based sample size (appendix p 8). Clinical observers worked in shifts, covering 24 h each day. Separate groups of data collectors were responsible for observation and verification, exit survey, and routine register data extraction. We used an Android-tablet-based electronic data capture system that was custom built and designed to restrict access by data collector group but linked records at an individual level.28,31 All data were stored locally on the tablet and synchronised to a country database server managed in Microsoft SQL. A centralised

Panel: Service delivery contexts and selected interventions

Labour and delivery ward
(1) Uterotonics to prevent post-partum haemorrhage, (2) early initiation of breastfeeding, and (3) neonatal resuscitation by bag-mask ventilation. Eligible women and their newborn babies were observed while admitted on the labour ward. Exclusion criteria at admission no fetal heartbeat heard or imminent birth.

Kangaroo mother care ward or corner
(4) Skin-to-skin contact or kangaroo mother care position between mother and baby. All mother and baby pairs who were admitted to the kangaroo mother care ward or corner were eligible for observation and exit survey.

Newborn care ward or paediatrics ward
(5) Antibiotic treatment for neonatal infection. Infection diagnosis and name of injectable antibiotic treatment was verified from case notes because observation was not feasible.30 Eligible neonates were those admitted with clinically defined infection (sepsis, pneumonia, or meningitis). Antibiotic treatment was not documented in routine registers in these hospitals.

See Online for appendix
A web-based dashboard was developed to monitor the progress of data capture for selected interventions. Observation data regarding the interventions and practices were time-stamped, captured in real time by touching a specific data element: once for “observed done” and twice for “observed not done” to override the default “not observed”. Women’s responses to close-ended questions in the exit surveys regarding the interventions and practices were captured in real time and recorded as “yes”, “no”, or “don’t know, don’t remember”.

Health workers record each admitted individual woman and baby on one row in the routine registers and record data elements in columns that are either specific columns for that data element or non-specific columns (eg, other details). Research data collectors extracted intervention and practice data from these existing register records after hospital discharge, captured as “yes”, “no”, “not recorded”, or “not readable”. Registers were assessed according to two dimensions of data quality, completeness and external consistency with observation. If the register column was blank for an intervention, the column was extracted as “not recorded” in Tanzania and Nepal, but in Bangladesh as “no” (intervention not given) to align with register filling instructions. Hence calculating data element completeness in the Bangladesh registers was not possible. Bangladesh, Nepal, and Tanzania each had different routine register designs, all of which were paper based. The labour ward register design in Bangladesh changed during the study because of national standardisation. In the tables and figures we present data from the revised registers. Original and revised register design and data are shown in the appendix (pp 9–10). In Muhimbili, Tanzania, additional data elements were captured in a long-standing informal perinatal register.

Statistical analysis
Data were anonymised before pooling for analysis using Stata (version 14.2). To assess coverage for the selected indicators, we calculated observed, survey-reported, and register-recorded coverage (appendix p 11). We excluded participants with missing data from their relevant sample. For numerator validation, we used the
simplest denominator (total women observed, total births [livebirths plus stillbirths] observed, kangaroo mother care (KMC) mother–baby pairs observed, or newborn babies treated for infection). A comparison of denominators, including true denominators of clinical need where relevant, will be analysed subsequently. Often, population-based surveys (eg, DHS or MICS) measure coverage from “yes” responses, therefore “don’t know” and “no” responses might both be used to suggest no coverage. For registers, monthly data aggregation typically involves counting column ticks, so that “not recorded” is treated as “intervention not given”. In our analyses we present these typical scenarios and compare the effect on validity of excluding “don’t know” and “not recorded” responses (appendix p 12).

We calculated the absolute differences between observed coverage and exit-survey-reported and register-recorded coverage. Cut-off ranges were adapted from data quality review methods (overestimate or underestimate by 0–5%, 6–10%, 11–15%, 16–20%, and >20%) and used to generate heatmaps.32 To assess population-level validity for all indicators across both platforms (survey and registers) we calculated validity ratios, similar to verification factors in data quality review methods.32 Validity ratios can be applied when interventions and practices are intended for all women or newborn babies or a small target group. A ratio higher than 1·0 implies overestimation of survey-reported or register-recorded coverage compared with observed, and a ratio lower than 1·0 implies an underestimate. Ratio measure cut-offs used 0·05 increments, defining “excellent” as 0·95–1·05. Measures of individual-level validity were calculated as follows: when two-way table column totals were 10 or more we calculated sensitivity, and if relevant, specificity, negative predictive value, positive predictive value, area under the curve (AUC), and inflation factor. Otherwise we present percent agreement.28,30

Table 2: Individual-level validity testing for survey-recorded coverage versus observed coverage

Role of the funding source
The funder of the study attended the study design workshop but had no role in data collection, data analysis, data interpretation, or writing of the report. All authors had full access to all the data in the study and had final responsibility for publication submission decision.

Results
Between July 3, 2017, and May 30, 2018, among 23 015 women on the labour and delivery ward, 23 471 births were observed, 20 632 (89·6%) women had an exit survey, and 22 002 (95·6%) had register data.
Birth outcomes and background characteristics are shown in the appendix (pp 15–16). Women younger than 19 years comprised 4·6–17·2% of the sample and secondary education completion varied between sites (34·8–61·2%). Caesarean sections were done for 6698 participants, ranging from 7·0% in Temeke, Tanzania, to 72·8% in Azimpur, Bangladesh (appendix p 15–16). The proportion of in-hospital stillbirths ranged from three per 1000 to 49 per 1000 total births and the proportion of newborn babies with low birthweight (<2500 g) ranged from 7·4% to 26·5% (appendix p 16).

Survey-reported coverage of uterotonics for prevention of post-partum haemorrhage was 84·7% (95% CI 79·1–89·5), compared with observed coverage of 99·4% (98·7–99·8; table 1). Exit survey heterogeneity was low ($\tau^2$ 0·027), with 8·7% (4·5–14·1) of responses given as “don’t know” (appendix p 24). At the individual validity level, sensitivity of survey-reported coverage of uterotonics was 84·9% (79·6–89·6) and specificity 32·5% (21·2–44·6; table 1). Exclusion of “don’t know” responses resulted in sensitivity increasing to 93·5% (91·1–95·5) and specificity decreasing to 17·3% (7·4–24·4; appendix p 24).

Register-recorded coverage of uterotonics for prevention of post-partum haemorrhage was 77·9% (95% CI 37·8–99·5) with high heterogeneity ($\tau^2$ 0·729) between hospitals, compared with observed coverage of 99·2% (98·6–99·7; table 2; appendix pp 17, 24). In the hospital in Pokhara, Nepal, the register had no column to capture uterotonics, all other hospitals used specific columns. Temeke, Tanzania underestimated coverage by 1·7% and Azimpur overestimated by 0·5% (appendix pp 17, 24, 29). However, different hospitals in these countries using the same registers underestimated coverage, by 78·2% in Kushtia and by 33·9% in Muhimbili. At the individual validity level, sensitivity was 78·0% (37·8–99·5) and specificity 22·8% (1·7–53·6). Exclusion of “not recorded” records resulted in sensitivity increasing to 86·1% (48·5–100·0) and specificity decreasing to 3·5% (0·0–17·2). Register-recorded coverage of uterotonics after caesarean birth was 68·5% (15·5–100·0) compared with observed coverage of 99·4% (98·7–99·9), and after vaginal birth was 86·6% (55·0–100·0) compared with observed coverage of 99·4% (98·7–99·9; figure 2; appendix p 24).

Validity ratios for coverage of uterotonics by exit survey were “very good” in Temeke, Tanzania, “good” in Kushtia, Bangladesh, and “moderate” in the remaining three sites. Register validity ratios for coverage of uterotonics were “excellent” in Azimpur and Temeke, but “poor” in Kushtia, and Muhimbili (figure 3).

Among newborn babies who were observed for more than 1 h after birth (n=6304), exit survey interviews were done at mean 1·4 days (SD 2·9) after birth (appendix p 8). Consent was not granted by 87 (0·4%) women for observation and 416 (1·8%) for exit survey. 1967 (8·5%) women left the hospital before the survey could be done.

Figure 2: Coverage for five selected indicators measured by observation, register, and survey, overall and by mode of birth

Labour and delivery ward (n=23 015; A), KMC (n=840; B), verified neonatal infection (n=1015; C). Error bars show 95% CI. Pooled using random effects meta-analysis. Site-specific results by mode of birth are given in the appendix (pp 21–22). KMC=kangaroo mother care.
overestimated the coverage of breastfeeding initiated within 1 hour after birth compared with observed coverage (table 1). Exit survey heterogeneity was low (τ² 0·101), with 0·6% (95% CI 0·1–1·3%) of responses “don’t know” (appendix pp 17, 31, 36). Survey-reported coverage of early breastfeeding after caesarean birth was 17·1% (2·3–41·3), compared with observed coverage of 2·4% (1·2–3·9) and 69·5% (60·5–77·9) after vaginal birth, compared with observed coverage of 14·4% (5·4–26·7; figure 2, appendix pp 31, 36). Validity ratios for both survey and registers were categorised as “poor” in all sites (figure 2).

Exit survey-reported coverage underestimated bag-mask ventilation compared with observed coverage, using a total birth denominator (table 1). Survey heterogeneity was low (τ² 0·003) with 5·9% (95% CI 2·4–10·7) of responses “don’t know” (appendix pp 18, 38, 43). Sensitivity was 9·3% (4·7–15·0) and specificity was 99·5% (99·2–99·8; table 1). Exclusion of “don’t know” responses resulted in sensitivity increasing slightly to 12·5% (6·5–19·9) with no decrease in specificity (appendix pp 38, 43). Survey-reported coverage of bag-mask ventilation after caesarean birth was 0·4% (0·2–0·8), compared with observed coverage of 3·7% (0·9–8·3), and after vaginal birth was 1·1% (0·5–2·0), compared with observed coverage of 5·0% (2·3–8·6) (figure 2, appendix pp 38, 43).

Register-recorded coverage underestimated bag-mask ventilation, with low heterogeneity (τ² 0·017), compared
with observed coverage (table 2; appendix pp 18, 38). Register column design varied (figure 4). In Bangladesh, the column was ticked when bag-mask ventilation was done and was otherwise left blank, and coverage was slightly overestimated by 0.1–1.6% (figure 4). In Tanzania, a numerical code (“3” for bag-mask ventilation) or “no” was written in the column, and completeness was 55.7% for Muhimbili and 91.1% for Temeke (appendix pp 38, 43). The Pokhara register did not capture this data element. Sensitivity was 23.6% (95% CI 7.3–45.2) and specificity was 96.8% (94.2–98.7; table 2). Exclusion of “not recorded” records resulted in sensitivity increasing to 53.6% (28.1–78.1) and specificity decreasing to 77.7% (57.9–92.5; appendix pp 38, 43). Register-recorded coverage of bag-mask ventilation after caesarean birth was 3.2% (0.9–6.7),
compared with observed coverage of 4.1% (0.6–10.4), and after vaginal birth register-recorded coverage of bag-mask ventilation was 5.9% (3.6–8.9), compared with observed coverage of 5.9% (3.3–9.2; figure 2, appendix pp 38, 43). Survey validity ratios were all categorised as “poor” (figure 3). For register validity ratios, Azimpur was “good” but all other sites were “poor” (figure 3).

In KMC wards or corners, 840 mother–baby pairs, including 91 babies who were born outside of the study hospital, were observed, with 652 exit surveys done and 813 routine register records extracted (figure 1). 815 (97%) of KMC babies had a birthweight of 2000 g or less (WHO recommendation or KMC). Background characteristics are shown in the appendix (p 45). Pre-discharge mortality was low (0.0–1.8%; appendix p 45).

Exit survey-reported coverage of KMC was 99.9% (95% CI 98.3–100), compared with observed coverage of 100% (99.9–100), and sensitivity was 100% (99.9–100), with zero “don’t know” responses (table 1). KMC coverage was captured in specific national standardised KMC ward registers, except in Nepal, which used the general child register (figure 4). Register-recorded coverage from standardised specific KMC registers was 92.9% (84.2–98.5), with low heterogeneity (I² 0.065), compared with observed coverage of 100% (99.9–100) and sensitivity of 93.0% (84.2–98.5; table 2; appendix pp 19, 46, 48). Validity ratios for KMC by exit surveys were categorised as “excellent” for all sites, except Azimpur, which was “good”, and for registers validity ratios were “excellent” in the Bangladesh sites and good in the Tanzania sites and for KMC in Pokhara (appendix pp 55–56). Register completeness comparison, before and during the study, revealed decreases of more than 5% for bag-mask ventilation coverage in both Tanzanian sites and for uterotonics in Muhimbili. Breastfeeding completeness increased in Muhimbili from 0 to 99.4% (appendix p 54).

Discussion

We examined validity of coverage indicators for selected maternal and newborn care indicators in two data systems: exit surveys and routine registers. Surveys are highly standardised in question design and interview technique. Registers are variable in design and filling techniques. We found much higher heterogeneity for register-recorded coverage compared with exit-survey reported coverage. Even with the same register design, accuracy varied between hospitals, with good validity for the highest performing sites. We stratified data by mode of birth and found that caesarean birth affected measurement in surveys and registers. With rising caesarean rates, especially in LMICs, this finding needs further consideration. Register data that are aggregated for use are typically located in the labour and delivery ward, but with high caesarean section rates, specific registers in operating theatres might be necessary. For survey reports after caesarean birth, low accuracy might relate to not seeing an intervention happening (eg, whether or not the baby had bag-mask ventilation) but might also be a reflection on gaps in respectful care; women have a right to communication and informed consent regarding care for themselves or their newborn babies.

Survey report had low accuracy for indicators of clinical intervention coverage led by health workers around the time of birth, notably neonatal care, and to a lesser extent for uterotonics. This study is the first to test the validity of survey reporting of indicators of care for small and ill newborn babies. We found that survey reporting of bag-mask ventilation coverage had low accuracy and reporting of neonatal infection treatment with antibiotics had low sensitivity among the target group. By contrast, KMC, which is led by the woman had high sensitivity in exit surveys, with potential for further testing, including report from women did not practice KMC. Use in population-based surveys would require sufficient sample size for the target group of small babies requiring KMC. For neonatal infection, even interviewing only women whose babies had been admitted, we found high proportions of “don’t know” responses and underestimates of observed coverage. A high proportion of “don’t know” responses suggests that the survey question is a poor way of measuring intervention coverage. We reported “don’t know” as “no” in line with the practice of the DHS and
MICS for yes or no questions, but we note that sensitivity increased when “don’t know” responses were excluded for uterotonics and bag-mask ventilation coverage. Our exit survey had a recall period of a few days, but most household surveys cover the previous 2–5 years; other studies have found recall decay even by 1 year.6 Hence, these results are likely to be worse in a routine household survey.

Early breastfeeding rates were observed to be very low across study hospitals, particularly after caesarean. The early initiation of breastfeeding indicator is already measured in the DHS and MICS household surveys, and national and global tracking rely on these data.37,38 Our results indicate that both women’s report and routine register data substantially overestimate coverage. This finding is in agreement with previous validation studies.32-35 One register validation study for early breastfeeding in a composite indicator of essential newborn care also showed overestimation.24 We postulate three explanations for these overestimates: first, this finding might be due to the timing component (ie, breastfeeding early but not within 1 h) being misreported by the woman or health worker. Second, successful initiation of breastfeeding is a process that involves the baby being put to the breast, then attachment, and then sucking. Putting the baby to the breast is one important step and is the focus of the survey-reported question, but might not have been considered as initiation by the observer. The observers were trained to click the stamp on the tablet at the point of initiation and recording is likely to vary given the challenges of observing this complex and dynamic process. Third, the overestimate might be due to social desirability bias among women to over-report in surveys or professional desirability pressure on the health worker to over-record in registers. More work is needed to improve measurement of this crucial indicator, including exploring whether changing the timing component could increase accuracy in surveys and registers. In Muhimbili, before and during the study, register data completeness for breastfeeding increased from 0 to 99%. This finding was probably due to the data being extracted from the informal perinatal register before the study, rather than the formal labour ward register, and highlights how complex documentation systems affect measurement.

Registers have unrealised potential as a useful data source, shown by the high accuracy and sensitivity for indicators in some EN-BIRTH study hospitals. Although hospital registers can only capture a limited number of data elements, we found that register designs in Tanzania and Bangladesh already have the relevant numerator or count data for selected indicators of maternal and newborn health coverage.25 Many data are already being collected by frontline health workers. Register data were highly complete, and although data collectors rarely indicated data were not readable, we found low inter-rater χ results across register recorded data. Extracting data for aggregation is a crucial step for data flowing to higher levels in the health system, and more research is needed to inform data extraction quality. The accuracy of register-recorded coverage varied between hospitals even with identical register design, reflecting variation in implementation and data culture.39 In both Bangladesh hospitals, register-recorded coverage increased in the revised registers when specific columns for data elements replaced absent or non-specific columns in original registers; however, change in accuracy varied by indicator. Sensitivity increased (and specificity decreased) when “not recorded” data were excluded from analyses (eg, uterotonics and bag-mask ventilation). Further work on register design for high quality monthly data aggregation, as well as feedback after use, is needed.40 Qualitative research might help to understand the differences in these five hospitals by exploring barriers and enablers to routine documentation, specifically for register design, register filling, and register use.28

EN-BIRTH study strengths include multi-country sites, rigorous observational design, and large sample size (about 10-times higher than that in previous validation studies12-15,24) targeting previously missed clinical care groups, especially small and ill newborn babies—a priority in universal health coverage measurement.36 Errors were minimised in observation data by the tablet-based app design, which was custom-built and user friendly, with major effort invested in being able to navigate between the recording of simultaneous events for the woman and baby with minimal delay.37 The tablet app also importantly captured time-stamped data for time-sensitive interventions, around the time of birth when complications might mean that women can die within hours and babies within minutes. Detailed analyses, including quality of care with timing data, are published separately.38-40 Dual observation by supervisors showed high or substantial agreement for most data elements, with breastfeeding coverage scoring the least well across all sites, probably due to challenges of capturing the process. Information bias during data collection was reduced by using different data collector groups for observation, exit surveys, and register data extraction. The effect on register recording completeness from the presence of researchers was assessed by comparison with register data extraction before the study.27 As per protocol, we did not base our assessment of validity using AUC cut offs because our data were all binary (yes or no) for the coverage estimates; thus, the AUC is simply the average of the sensitivity and specificity.28 P estimates the percentage of variation that is attributable to study heterogeneity. For an intervention like uterotonics that was almost universally applied, there is little total variation so that even small differences between sites result in a large P. We therefore chose to place more emphasis in R², which provides an estimate of the magnitude of the between-site variation. A small value
of τ² indicates little absolute variation between sites even when \( P \) might appear large.

However, our study also had limitations. Despite large samples, we did not achieve ten or more column counts in the two-way tables for all indicators, either because interventions had very high coverage (eg, correctly provided for all women and babies) or very low prevalence (eg, small clinical target group). This affected our ability to report on individual-level validity metrics. By contrast with other measurement validation studies, EN-BIRTH chose to use vigorous subset double observation inter-observer \( \kappa \) calculations to assess possible between-site variation in validation results. In the protocol, we pre-defined ranges for what would be considered high or substantial agreement. \( \kappa \) scores were lower than expected for some indicators in some sites. We postulate that this finding might be a real reflection of inter-observer variation, and we suspect this to be the case, for example, regarding breastfeeding in Temeke, with the lowest percent agreement and a low \( \kappa \). We note the dependence of \( \kappa \) on prevalence with paradoxically low \( \kappa \) scores, due to the imbalance in marginal totals or with perfect symmetry in the imbalance, as our results showed.\(^4\) The tablet app was not available for pre-study extraction of register data, and the different data collection methods might account for some of the differences in completeness before and during the study.

The five hospitals were high-volume public comprehensive emergency obstetric and neonatal care hospitals in cities and results might not be generalisable to lower-level or rural facilities with lower volumes. The study sample might have been healthier than is typical in such hospitals because recruitment excluded antepartum intrauterine fetal death and women who were too ill to consent after admission. This observational study was not designed to capture true denominators in terms of the need of intervention required for coverage indicators—eg, for accurate diagnosis of neonatal sepsis in terms of microbiological culture or molecular diagnosis. Although blood culture is still considered the definitive diagnostic method, even with excellent laboratory capacity, only about a third of neonatal sepsis cases have a positive culture result. The focus of this study was validity of routine health system data, especially of the clinical diagnosis, and was not addressing the need for better laboratory systems, which is also crucial.\(^5\)

Time pressure on health workers in these busy hospitals might have affected their ability to deliver and communicate care to women, affecting exit survey reports and register documentation.\(^6\) We consider this real-world time pressure to be present in many such contexts. Women’s reports were collected at hospital exit, close in time to the event and without the typical 2–5 year gap in household surveys. If women cannot report accurately at exit from the facility, they are unlikely to report more accurately later in a household survey, so exit survey findings are relevant when considering adding questions to household surveys.\(^7\) The EN-SMILING study is following up with the cohort, with the potential to repeat interviews in 5 years to investigate the change in women’s report.\(^8\)

Policymakers and programme managers require information to inform investments and programmatic course correction. Surveys are important in most LMICs for population-based outcome data and contact coverage of care, but given the high rate of “don’t know” responses and low accuracy for the reporting of clinical interventions, adding these indicators to surveys is not justifiable. Because approximately 80% of births worldwide are now in facilities, standardising register design and linked information systems have the potential to sustainably improve data quality for care at birth. Routine register data can be accurate and health workers’ time investment would not be wasted if these data were better used. Well-designed, standardised registers are important, and could reduce the burden on health workers of duplicative, or non-valid, data collection.\(^2\) If interventions and practices are defined with a timing element (eg, early initiation of breastfeeding), this inclusion needs consideration in register design. The timing component of the uterotonics coverage indicator is not yet clearly defined, which will limit comparability if routinely measured. EN-BIRTH tested validity of measurement in paper-based registers at the interface with women and their babies. A further phase will explore the feasibility of these indicators flowing up through the national routine data systems, many of which are being rapidly digitised.\(^2\) Another important research gap is how to best measure experience of care, including respectful care in all settings, and the provision and experience of care for women and newborn babies in fragile and humanitarian settings.\(^3\,\,5\,\,30,\,31\)

Valid routine data alone will not save lives. Data need to be used by health-care professionals caring for women and their babies, and by policy makers and governments to invest and transform care, enabling universal health coverage as a reality that can be measured and improved.

**Contributors**

JEL conceived the EN-BIRTH study, acquired the funding and led the overall design. QS-uR was the main lead for analyses, working closely with LTD and the EN-BIRTH team. LTD and JEL drafted the manuscript with the principal investigators: SEA, AKC, HM, AER, NS, and country teams. All authors made substantial contributions to conception, design, data collection, analysis, or interpretation of data. GRG-L did the analysis for register recording practice comparison before and during the study. All authors revised the manuscript and gave final approval for publication and agree to be accountable for the work. Collaborative authors including the Expert Advisory Group made contributions to conception, design, data collection, analysis, or interpretation of data. The authors’ views are their own, and not necessarily from any of the institutions they represent.
