The magnetic properties and electronic structures of pure, doped and defective cerium oxide (CeO<sub>2</sub>) have been studied theoretically by means of *ab initio* calculations based on the density function theory (DFT) with the hybrid HF/DFT technique named PBE0. Carbon (C), nitrogen (N), phosphorus (P), sulphur (S), lanthanum (La) and praseodymium (Pr) doped in CeO<sub>2</sub> and CeO<sub>2</sub> containing oxygen vacancies (O<sub>v</sub>) were considered. Our spin-polarized calculations show that C, N, Pr dopants and O<sub>v</sub> defects magnetize the non-magnetic CeO<sub>2</sub> in different degree. The optical band gap related to photocatalysis for pure CeO<sub>2</sub>, corresponding to the ultraviolet region, is reduced obviously by C, N, S, Pr impurities and oxygen vacancies, shifting to the visible region and even further to the infrared range. Especially, N-, S- and Pr-doped CeO<sub>2</sub> could be used to photocatalytic water splitting for hydrogen production. As the concentration of O<sub>v</sub> increasing up to 5%, the CeO<sub>2</sub> exhibits a half-metallic properties.

CeO<sub>2</sub>, as one of the most important rare-earth metal oxides, has been in focus of intensive research during recent years due to its wide range of industrial applications. CeO<sub>2</sub> special feature of high reactivity mediated by redox couple of Ce<sup>4+</sup>/Ce<sup>3+</sup> could be used in catalysis<sup>1,2</sup>. Its unique oxygen storage capacity<sup>3</sup> could make CeO<sub>2</sub> material for solid oxide fuel cells<sup>4</sup>. Another potential application of CeO<sub>2</sub>-based materials is in spintronics devices with advanced silicon based microelectronic devices<sup>5</sup>, due to an excellent match of crystal structure and high dielectric constant ( $\epsilon = 26$ ) of CeO<sub>2</sub> with those of silicon<sup>6</sup>.

CeO<sub>2</sub> is also a potential material for ultraviolet (UV) filtration<sup>7</sup>. CeO<sub>2</sub> with a band gap of 3.2 eV, good transparency in the visible range, and no known toxicity, seems to be a promising inorganic material for use as a UV filter in sunscreen cosmetic products. Some previous studies regarding Zn-, Mg- and Ca-doped CeO<sub>2</sub> demonstrated that the impurities shift the material's band gap because of their effects on electronic transitions<sup>8</sup>. Furthermore, CeO<sub>2</sub>, as a wide band-gap semiconducting material which absorbs light in the near UV and slightly in the visible region, is a prospective material used in photocatalytic reactions, such as decomposing water to produce hydrogen and oxygen<sup>9</sup>. One of the most effective methods is doping. Zr- and La-doped CeO<sub>2</sub> have found their potential application in solar cell devices<sup>10</sup>, Mao *et al.* demonstrated that N-doped CeO<sub>2</sub> shows a visible-light absorbance shift<sup>11</sup>.

As mentioned above, the oxygen storage capacity of CeO<sub>2</sub> makes it an important material. By releasing and storing oxygen during fuel-rich and lean conditions, an optimal oxygen pressure for the catalytic removal of harmful exhaust gases can be maintained. This is achieved by partial reduction/oxidation of the CeO<sub>2</sub> and is related to the chemistry of oxygen vacancies in the material<sup>12</sup>. However, the description of oxygen vacancies in insulating transition and rare earth metal oxides is a challenge for modern electronic structure calculations<sup>13</sup>. In this paper, we used first-principles method to investigate the magnetic properties and electronic structures for doped and defective CeO<sub>2</sub>. Carbon (C), nitrogen (N), phosphorus (P), sulphur (S), lanthanum (La) and praseodymium (Pr) doped in CeO<sub>2</sub> and CeO<sub>2</sub> containing oxygen vacancies (O<sub>v</sub>) were considered.

**Figure 1.** (a)  $\text{CeO}_2$  crystal with  $Fm\bar{3}m$  structure (big green and small red spheres represent Ce and O atoms respectively). Spin-charge density ( $n_\alpha - n_\beta$ ) maps for C- (from the (001) side view) (b), Pr-doped (from the (110) side view) (c), and  $1O_v$  (from (110) side view) (d) defective  $\text{CeO}_2$ .

## Results

**Magnetic properties.** Cerium oxide ( $\text{CeO}_2$ ), or ceria, is a lanthanide oxide with a cubic fluorite structure ( $Fm\bar{3}m$ ) and a cell parameter of 5.41 Å at room temperature, in agreement with our PBE0 result of 5.49 Å, as shown in Fig. 1(a).

First, we investigated the magnetic properties of pure, doped and defective  $\text{CeO}_2$ . Table 1 lists the magnetic moment of doped and defective  $\text{CeO}_2$ , and shows that C, N and Pr dopants and O vacancies ( $O_v$ ) magnetize the pure  $\text{CeO}_2$  in different degree. C impurity introduces a global magnetic moment of  $2.0 \mu_B$  per supercell. The C atom does the most contribution ( $0.733 \mu_B$ ) to the total magnetic moment, and the four nearest Ce and six next-nearest neighboring O atoms provide  $0.090 \mu_B$  per Ce and  $0.035 \mu_B$  per O, respectively. Spin-polarized charge density calculation indicates that C  $2p$  electrons diffuse to the second-nearest neighboring O atoms and lead to a polarization of surrounding O and Ce atoms, implying FM coupling between the doped C atom and its neighboring atoms (see Fig. 1(b)). N impurity magnetizes the pure  $\text{CeO}_2$  with a magnetic moment of  $1.0 \mu_B$  per supercell, being smaller than that of C dopant. The N atom and six second-nearest O atoms contribute  $0.563 \mu_B$  and  $0.048 \mu_B$  per atom to the total magnetic moment respectively, whereas the spin-polarized contribution from the nearest Ce could be neglected. In a defective  $\text{CeO}_2$  system containing oxygen vacancies, two unpaired electrons localize in one  $O_v$ , leaving cation dangling bonds. When the  $O_v$  site is occupied by the C or N dopant, the two unpaired localized electrons fulfill  $2p$  orbitals of the dopant, and according to Hund's rules, the substitutional C or N has four or five  $2p$  electrons with high-spin configuration of  $2p^4$  ( $\uparrow\uparrow\uparrow$ ) for C or  $2p^5$  ( $\uparrow\downarrow\uparrow\downarrow$ ) for N, which may create magnetic moment of  $2.0 \mu_B$  or  $1.0 \mu_B$  per impurity atom. Additionally, we found that P and S dopants do not produce spin-polarization in pure  $\text{CeO}_2$ . For the P-doped case, according to effective charge calculation,  $3p$  electrons of the P impurity are much more delocalized than in the N-doped case, which leads to a vanishing of spin polarization.

We have also calculated La- and Pr-doped  $\text{CeO}_2$ , to investigate the magnetic properties affected by lanthanide elements. From our calculations, La does not introduce spin polarization, whereas Pr magnetizes the doped  $\text{CeO}_2$  with a magnetic moment of  $1.0 \mu_B$  per supercell. For the Pr-doped  $\text{CeO}_2$ , the localized  $4f$  electrons do the most contribution ( $1.211 \mu_B$ ) to the magnetization and the  $2p$  electrons of the eight nearest O atoms occur opposite spin polarization with a non-negligible magnetic moment of  $-0.032 \mu_B$  per O (see Fig. 1(c)). On the other hand, the

**Table 2.** Band gaps (between the top of occupied states and the bottom of unoccupied states) of doped and defective CeO<sub>2</sub> (eV). For the spin-polarized cases, spin-up and spin-down states are labeled with  $\alpha$  and  $\beta$  respectively. The supercell containing 1, 2, 3 and 4 oxygen vacancies are labeled with 1O<sub>v</sub>, 2O<sub>v</sub>, 3O<sub>v</sub> and 4O<sub>v</sub>, respectively.

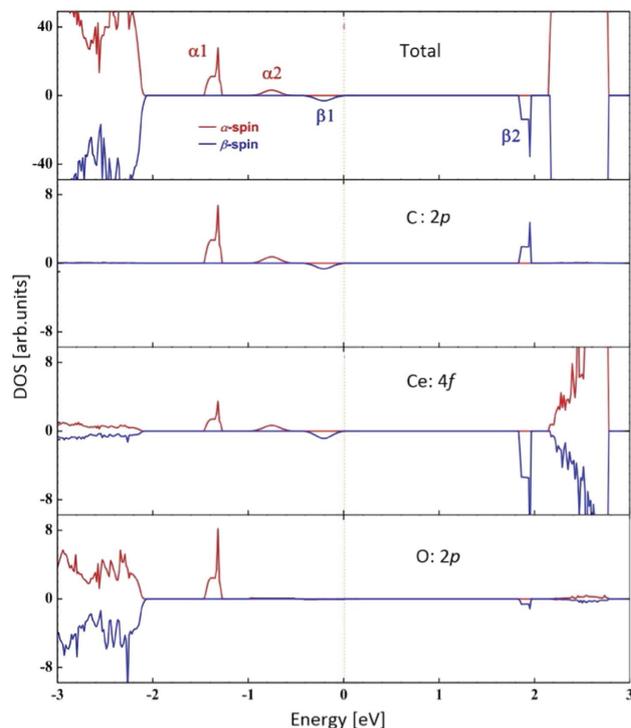

La-doped CeO<sub>2</sub> has no magnetizing phenomenon, and it is mainly due to the unpaired electron delocalization, being responsible for spin pairing.

Furthermore, we investigated the defective CeO<sub>2</sub> system containing oxygen vacancies (O<sub>v</sub>). For the non magnetic CeO<sub>2</sub>, the formation of an O<sub>v</sub> is known to result in the donation of two electrons which results in magnetism. Thus, upon O<sub>v</sub> formation in CeO<sub>2</sub>, two electrons are left behind, and they localize on the *f*-level traps of the neighbouring Ce atoms, introducing two unpaired electrons which magnetize the defective CeO<sub>2</sub>. According to our calculations, the defective CeO<sub>2</sub> containing 1, 2, 3 and 4 O<sub>v</sub>s introduces 2.0, 4.0, 6.0 and 8.0  $\mu_B$  magnetic moment per supercell, respectively. Our spin charge calculations demonstrate that the *f* electrons localizing on the neighbouring Ce atoms result in the spin polarization (see Fig. 1(d)).

**Electronic structures and photocatalysis.** Next, we mainly focus our discussion on band gaps and electronic structures of pure, doped and defective CeO<sub>2</sub> systems. Our hybrid-DFT calculation for the band gap of pure CeO<sub>2</sub> gives an overestimating value of 4.24 eV, compared to the experimental value of 3.2 eV<sup>10</sup>. Density of state (DOS) calculations demonstrate that the top of valance bands (VB) mainly consist of O 2*p* orbitals and the bottom of conduction bands (CB) primarily is formed by Ce 4*f* orbitals. Table 2 collects all the band gaps between the top of occupied states and the bottom of the unoccupied states for doped and defective CeO<sub>2</sub>. For the C-doped CeO<sub>2</sub> system, four separated bands are introduced between the VB-CB gap. Because the C impurities magnetize CeO<sub>2</sub>, the band structure of C-doped system is polarized magnetically. Two bands are  $\alpha$ -spin states and others  $\beta$ -spin states, as we can see in Fig. 2. Fermi level is located at the top of  $\beta$ 1 band and the unoccupied  $\beta$ 2 band is below the CB bottom, which leads to a reduced gap of 1.85 eV corresponding to an optical absorption. The two  $\alpha$ -spin bands are all above the VB top and below the Fermi level, and the first possible optical absorption corresponds to an electron transition from the  $\alpha$ 2 band to CB bottom (2.68 eV) in  $\alpha$ -spin state. So, the C impurities considerably reduce the forbidden gap of pure CeO<sub>2</sub> by 37% for  $\alpha$ -spin and 56% for  $\beta$ -spin states. When the band gap is reduced, electrons from the VB top can migrate easily to the CB bottom by absorbing light, forming electron-hole pairs. The electrons and holes that accumulate on the surface of material are then scavenged by oxygen molecules (O<sub>2</sub>) and hydroxides (OH<sup>-</sup>) dissolved in water to yield highly oxidative species, such as superoxide radical anions (O<sub>2</sub><sup>•-</sup>) and hydroxyl radicals (<sup>•</sup>OH), which are responsible for decomposing and degenerating pollutants. Therefore, photocatalysis is closely related to the optical band gap of materials. C dopant shifts the optical response of CeO<sub>2</sub> from the UV to the visible region and change the photocatalytic properties of CeO<sub>2</sub>.

CeO<sub>2</sub> is not only a potential photocatalyst for water/air purification, but also a candidate used in photocatalytic water-splitting for hydrogen production. Both applications require essential photogeneration of electron-hole pairs, which is closely connected with the band gap. According to our calculations on C-doped CeO<sub>2</sub>, the bottom of unoccupied states of  $\alpha$ - and  $\beta$ -spin are both higher (negative) than hydrogen production level (E<sub>H<sub>2</sub>/H<sub>2</sub>O</sub>) by 2.5 eV for  $\alpha$ -spin and 2.2 eV for  $\beta$ -spin, meeting the requirement to initiate hydrogen production. On the other hand, the top of the occupied states located much higher than water oxidation level (E<sub>O<sub>2</sub>/H<sub>2</sub>O</sub>) for both spin states, which does not satisfy the requirement for effective water oxidation. However, the  $\alpha$ 1 occupied band is close to the E<sub>O<sub>2</sub>/H<sub>2</sub>O</sub>, being slightly higher by 0.3 eV. Though it also does not meet the water oxidation requirement, quite small difference and the ineluctable errors from theoretical calculations make C-doped CeO<sub>2</sub> a probable photocatalyst for hydrogen production.

DOS analysis shows that C and neighbour O 2*p* orbitals form the  $\alpha$ 1 band, and the unoccupied  $\beta$ 2 band consists of C 2*p* and the neighbour Ce 4*f* orbitals. The C 2*p* states lead to the neighbour O 2*p* electrons and Ce 4*f* orbitals separate from the VB top and CB bottom respectively, forming hybridization orbitals, as we can see Fig. 2. Spin-polarized DOS calculations also can reveal the magnetization mechanism. The number of spin-up electrons

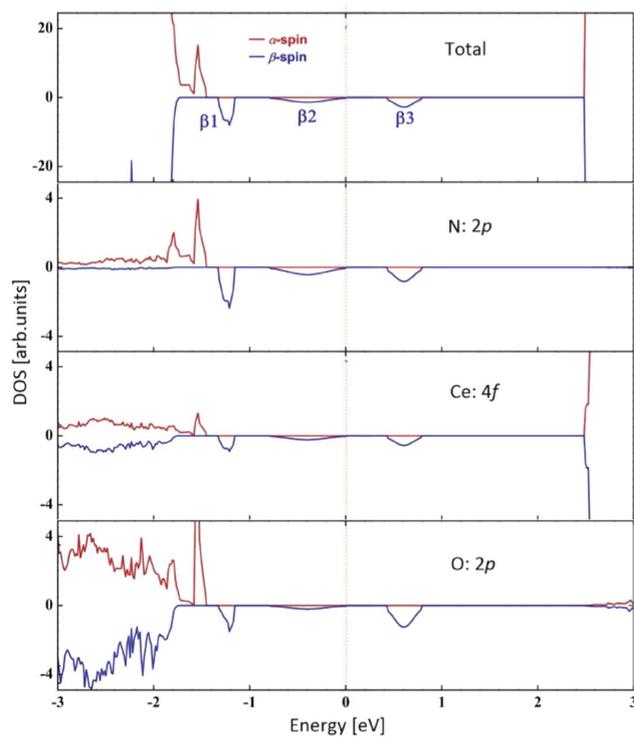

**Figure 2.** Total and partial spin polarized DOS for the C-doped  $\text{CeO}_2$ . The Fermi level is set to zero.

should be more than that of spin-down states for a system with net magnetic moment. For C-doped  $\text{CeO}_2$ , we found that there are obviously more  $\alpha$ -spin electrons near the Fermi level, where the C  $2p$ , neighbour O  $2p$  and Ce  $4f$   $\alpha$ -spin states are dominant. The integrated DOS calculations also demonstrated that the magnetism mainly results from the spin-exchange splitting between the  $\alpha$ - and  $\beta$ -spin states near the Fermi level. Similar scenario is also observed in other C- or N-doped systems<sup>14</sup>.

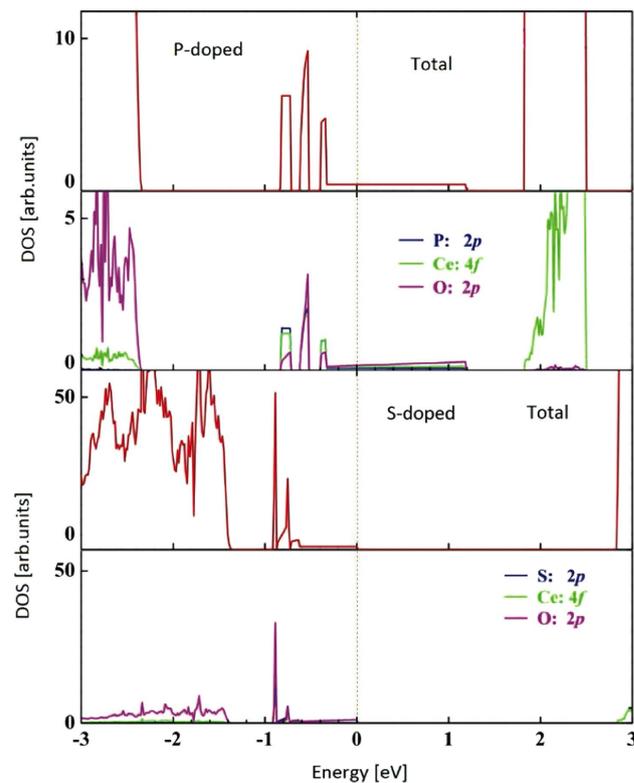

Figure 3 shows that there are three separated  $\beta$ -spin bands introduced between the VB-CB gap and one  $\alpha$ -spin band connected with the VB top for N-doped  $\text{CeO}_2$ . Fermi level is at the top of  $\beta 2$  band. The gap related to the  $\alpha$ -spin electron transition equals to 3.96 eV, being much larger than that of C-doped case and closing to the pure  $\text{CeO}_2$ , whereas the corresponding gap for  $\beta$ -spin state is only 0.47 eV (see Table 2). Similar to the C-doped case, N  $2p$  and the neighbour O  $2p$  orbitals do the major contributions to the impurity bands. The N impurities pull the neighbour O  $2p$  electrons from VB top towards Fermi level, however the affection on the neighbour Ce  $4f$  orbitals could be neglected (see Fig. 3). Therefore, a degree of hybridization between the N  $2p$  and neighbour O  $2p$  states can be seen near the Fermi level. The  $\alpha$ -spin gap related to photocatalysis meets the requirements for water splitting, whereas the slight reduction of the gap with respect to the pure  $\text{CeO}_2$  implies that photocatalytic water splitting occurs near the UV region. We found that occupied- $\beta 1$  band approximately lies at the same level as  $E_{\text{O}_2/\text{H}_2\text{O}}$ , and unoccupied- $\beta 3$  bands locates 0.46 eV above the  $E_{\text{H}_2/\text{H}_2\text{O}}$ . Therefore, the optical absorption corresponding to an electron transition from occupied- $\beta 1$  to unoccupied- $\beta 3$  bands (1.6 eV), which satisfies the conditions of photocatalytic water splitting, suggests that N-doped  $\text{CeO}_2$  could be applied in visible-region photocatalysis for hydrogen production.

P- and S-doped  $\text{CeO}_2$  do not exhibit the magnetization like C- and N-doped cases, thus the band structures are not spin-polarized. P impurities introduce three separated bands between the VB-CB gap. Two of them are narrow and below the Fermi level, and the third band is expanded and crosses the Fermi level with a tail, which shows a degree of metallic properties, as we can see in Fig. 4. For the S-doped  $\text{CeO}_2$  system, there are also three approximately separated bands introduced between the VB-CB gap. The two lower bands are narrow and the third impurity band is expanded but does not cross the Fermi level, unlike the P-doped case, still showing insulating properties (see Fig. 4). The gap between the top of occupied states and the bottom of unoccupied states is 2.85 eV, reducing the VB-CB gap of pure  $\text{CeO}_2$  considerably by around 33%. On the other hand, the first impurity band for the P-doped case locates above the VB top 1.55 eV, being much higher than that of the S-doped case (0.49 eV), which implies that P  $3p$  orbitals are more delocalized. Similar to the C- and N-doped cases, for P- and S-doped  $\text{CeO}_2$ ,  $3p$  orbitals of dopants, neighbour O  $2p$  and Ce  $4f$  orbitals hybridize to the impurity bands located between the VB-CB gap. For the S-doped case, our calculations show that the occupied impurity bands lie closely to the  $E_{\text{O}_2/\text{H}_2\text{O}}$  and the CB bottom is much higher than the  $E_{\text{H}_2/\text{H}_2\text{O}}$  level, indicating a probability for water spitting.

Lanthanide impurities, such as La and Pr, change the band and electronic structures of pure  $\text{CeO}_2$ . We found that unlike the above-mentioned dopants, La impurities do not introduce separated bands between the VB-CB gap. There are a few states crossing the Fermi level, exhibiting a little metallicity for the La-doped  $\text{CeO}_2$  system, as

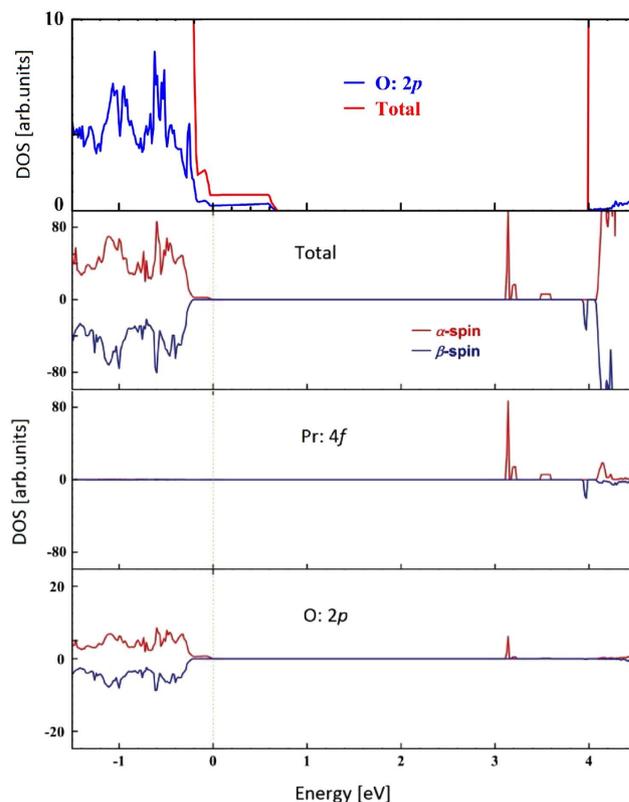

**Figure 3.** Total and partial spin polarized DOS for the N-doped  $\text{CeO}_2$ . The Fermi level is set to zero.

**Figure 4.** Total and partial DOS for the P- (up) and S-doped (down)  $\text{CeO}_2$ . The Fermi level is set to zero.

we can see Fig. 5. O  $2p$  states forming the VB top in pure  $\text{CeO}_2$  are pulled towards the Fermi level by La  $4f$  and  $5p$  orbitals, leading to a degree of  $p$ - $f$  hybridization straddling the Fermi level. The electronic structure of Pr-doped

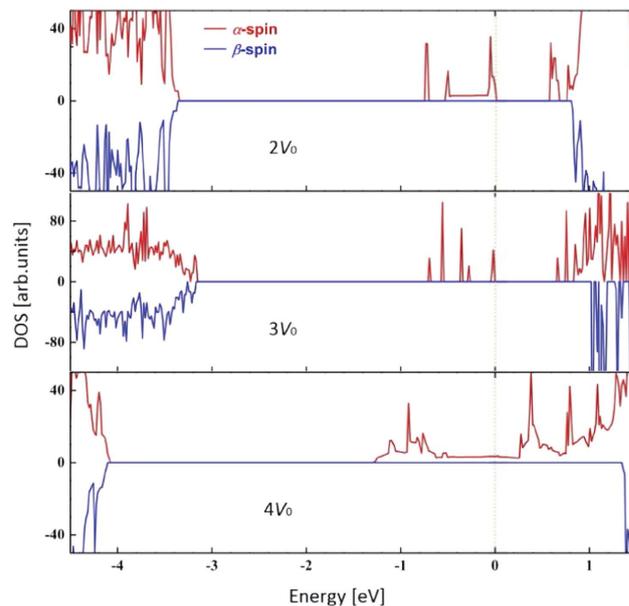

**Figure 5.** Total and partial DOS for the La- (up) and Pr-doped (down)  $\text{CeO}_2$ . The Fermi level is set to zero.

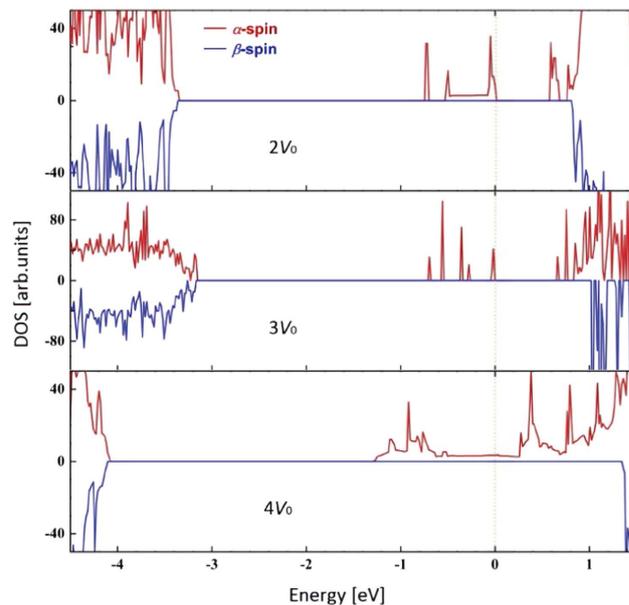

$\text{CeO}_2$  is quite different from that of La-doped case. Pr dopants magnetize the doped  $\text{CeO}_2$  system and polarize the band structure. Four separated vacant bands are introduced between the VB-CB gap, being far from the Fermi level and closing to the CB bottom (see Fig. 5). Three of them are  $\alpha$ -spin states and the other is  $\beta$ -spin. The three  $\alpha$ -spin bands lie below the  $\beta$ -spin band. The gap between the top of occupied and the bottom of unoccupied states, corresponding to an optical absorption, is 3.12 eV for  $\alpha$ -spin and 4.17 eV for  $\beta$ -spin states, reducing the VB-CB gap of pure  $\text{CeO}_2$  by around 26% and 2% respectively. Because of the obvious reduction of the optical gap in  $\alpha$ -spin state, photocatalysis in the visible region is possible for the Pr-doped  $\text{CeO}_2$  case. Further, the top of occupied states locate 0.3 eV below the  $E_{\text{O}_2/\text{H}_2\text{O}}$  and 1.6 eV above the  $E_{\text{H}_2/\text{H}_2\text{O}}$  level, meeting the water-spitting requirements. Therefore, Pr-doped  $\text{CeO}_2$  also could be used in hydrogen production. DOS calculations demonstrate that these separated vacant bands mainly consist of Pr 4*f* orbitals and the contributions from other orbitals could be neglect, therefore the *f-p* hybridization is not remarkable for these bands. We also found that there are a few  $\alpha$ -spin states moving out of the VB top towards the Fermi level (see Fig. 5). A slight *f-p* hybridization between Pr and neighbor O exists near the Fermi level.

Further, we performed calculations on the supercell containing 1, 2, 3 and 4 oxygen vacancies (labeled with  $1\text{O}_v$ ,  $2\text{O}_v$ , ...) to investigate the electronic structure of defective  $\text{CeO}_2$ . For the  $1\text{O}_v$  case, two connected bands with  $\alpha$ -spin state lie 3.08 eV above the VB top, governing the Fermi level, and the gaps between the top of occupied and the bottom of unoccupied bands are 0.79 eV and 4.60 eV for  $\alpha$ - and  $\beta$ -spin states respectively (see Fig. 6). So, the  $\text{O}_v$  reduces considerably the optical gap (4.24 eV) by around 81% in one spin state, whereas slightly increases it in the other spin state. Therefore, the photocatalysis of  $\text{CeO}_2$  containing oxygen vacancies may even shift up to the infrared region. The formation of an  $\text{O}_v$  is known to result in the donation of two electrons which form the defect bands locating between the VB-CB gap. According to our DOS calculations, the defect bands show mostly neighbour Ce 4*f* character. Then we can conclude that the two electron left behind localize on the *f*-level traps of the neighbour Ce atoms.

For the  $2\text{O}_v$  and  $3\text{O}_v$  cases, there are several  $\alpha$ -spin bands lying between the VB-CB gaps, as we can see Fig. 7. The gaps with  $\alpha$ -spin state between the top of occupied and the bottom of unoccupied bands are 0.57 eV for the  $2\text{O}_v$  case and 0.64 eV for the  $3\text{O}_v$  case, even reducing the optical gap further. Both cases have separated vacant  $\alpha$ -spin bands below the CB bottom. Finally, for the  $4\text{O}_v$  case, corresponding to the defect concentration of around 5%, the defective  $\text{CeO}_2$  system shows an obvious half-metallic character (see Fig. 7). Therefore, the charge carriers within the defect bands are sufficiently mobile with an ideal 100% polarization, which meets the need for spin injection where a highly polarized spin current is desired.

**Figure 6.** Total and partial spin polarized DOS for the  $\text{CeO}_2$  supercell containing  $10V_o$ . The Fermi level is set to zero.

**Figure 7.** Total spin polarized DOS for the  $\text{CeO}_2$  supercell containing 2 (upper), 3 (middle) and 4 (lower)  $O_v$ s. The Fermi level is set to zero.

## Conclusions

We have investigated magnetic properties, band and electronic structures of pure, doped and defective  $\text{CeO}_2$ , such as C, N, P, S, La and Pr dopants, as well as  $O_v$  defects, in the framework of DFT using the hybrid functional technique PBE0. C, N, Pr impurities and  $O_v$  defects introduce magnetic moments of  $2.0 \mu_B$ ,  $1.0 \mu_B$ ,  $1.0 \mu_B$  and  $2.0 \mu_B$  per supercell with one dopant or defect, respectively. The calculations on the gap between top of occupied and bottom of unoccupied band, which corresponds to an optical absorption, demonstrated that C, N, S, Pr dopants and  $O_v$  defects reduces the band gaps evidently, showing a visible-light and even further infrared absorbance shift. It implies that the photocatalysis related closely to the optical absorption may occur in the visible region. Especially, N-, S- and Pr-doped  $\text{CeO}_2$  are promising photocatalysts for water splitting. As the concentration of  $O_v$  increasing up to around 5%, the  $\text{CeO}_2$  exhibits a half-metallic properties.

## Methods

We have studied the magnetic properties and electronic structures of doped and defective CeO<sub>2</sub> by performing first-principles calculations based on the DFT. *Ab initio* simulations were performed using the projector augmented wave (PAW) method<sup>15</sup> as implemented in the Vienna *ab initio* simulation package (VASP) code<sup>16,17</sup>. We have chosen the exchange-correlation functional proposed by Perdew *et al.* using the hybrid HF/DFT calculation denoted hereby PBE0<sup>18</sup>. For Ce atoms, we have used PAW potentials with following orbitals treated as valence states: 5s<sup>2</sup>5p<sup>6</sup>6s<sup>2</sup>4f<sup>1</sup>5d<sup>1</sup> configuration. The calculations were performed using a cutoff energy of 500 eV and sampling the Brillouin zone with fixed Monkhorst-Pack *k* points (3 × 3 × 3) for conventional cell and (5 × 3 × 1) for a 72-atom (1 × 2 × 3) supercell.

## Acknowledgements

Thanks to SSF-Sweden and NRF-Korea for joint collaborative research funding. This work was supported by the National Research Foundation of Korea(NRF) grant funded by the Korea government(MSIP) (No. 2015-066177). H. Shi was supported by NSFC Grant No. 11004008. SNIC, HPC2N and UPPMAX are acknowledged for providing computing time.

## Author Contributions

R.A. and W.L. designed and planned the research. T.H. performed the calculations. H.S. analyzed data and wrote the manuscript. R.A., W.L., T.H., H.S. and T.W.K. reviewed the manuscript.
